At the same period 612 endoscopic sphincterotomies were performed, in 321 cases – for reason of the bile duct stones. There was 56 per cent of patients over 65 years. Complications were evaluated – bleeding, acute pancreatitis and restenosis of Vater's papilla. The rate of mortality was 0·16 per cent. The cost of these two kinds of the treatment was compared. The endoscopic sphincterotomy one was over 10 times cheaper.

Conclusions: The authors believe that endoscopic sphincterotomy ought to be the main treatment of bile duct stones, particularly in patients with high operative risk.

The efficacy of laparoscopic surgery in thoracic and abdominal emergencies – preliminary report

B. Marţian, E. Nicolau, Ş. Jianu, F. Costea, R. Stănescu, C. Turculeţ, I. Lică, M. Avram, F. Iordache and Gh. Ionescu
Surgical Department, Emergency Hospital Bucharest, 8 Floreasca Avenue, 71406 Bucharest, Romania

The endoscopic surgical procedures extended to and began to dominate more and more surgical fields. Our paper desires to show as a preliminary report the experience of an Emergency Hospital in using laparoscopy and thoracoscopy in the large area of acute surgical diseases.

Material and methods: We propose a retrospective study dealing with 369 laparoscopic and thoracoscopic procedures performed between 1 January 1995 and 31 December 1997. All of them were acute conditions. We split the heterogeneous group in two main sections: traumatic and non-traumatic including 32, respectively 333 cases with the initial specification that all items concerning 250 cholecystectomies will be subject for other papers. The purposes of performing them in these mentioned circumstances were both diagnostic and therapeutic. The 32 abdominal injuries included 10 penetrating wounds and 22 blunt traumas all of the latter concerning polytraumatized patients considered not fit for CT. The other 333 were 250 acute cholecystites, 32 perforated peptic ulcer (PPU), 27 acute pelvic diseases, 9 acute appendicitis, 4 bowel occlusions, 4 acute peritonitis, 4 acute pancreatitis, 2 reoperations, 1 foreign abdominal body. The remaining 4 observations concern 4 thoracoscopic approaches, 2 for traumatic and 2 non-traumatic conditions.

Results: All endoscopic surgery procedures were successfully performed, meaning there was no missed injury. In the trauma patient group were: 24 pure (limited to inspection and drainage or followed by laparotomy) diagnostic and 8 therapeutic laparoscopies, with 2 conversions for the penetrating injuries (1 transgastric and 1 diaphragmatic wound), respectively 5 conversions for the blunt injuries (2 for ruptured spleen, 1 for ruptured liver, 1 for ruptured small bowel and 1 for ruptured diaphragm). The therapeutic laparoscopies included 3 phrenorraphies, 2 haepatorraphies, 2 liver cautery haemostasis. There was no postoperative morbidity and only one patient died because of severe brain injury. In the 83 non-traumatic patients (excluding cholecystitis) we performed 2 pure diagnostic laparoscopies (1 bowel infarction and 1 tuberculous peritonitis) and 78 therapeutic ones with 3 conversions (1 for massive uncontrolled haemoperitoneum in ectopic pregnancy, 1 for liver and peritoneal abscesses and 1 for acute extensive necrotizing pancreatitis). There was no mortality; morbidity consisted in 1 residual abscess and 2 ileus after laparoscopic suture of PPU.

Conclusions: Laparoscopy and thoracoscopy are very useful and safe when performed in selected cases of acute abdominal and thoracic diseases. In most instances it can be carried out on therapeutic definitive purposes without conversions, morbidity and mortality. The use in trauma patients is still limited, but efficacy consists both in possible accurate diagnosis and avoidance of unnecessary extended explorative laparotomy.

Right iliac fossa pain, post appendicectomy: the role of diagnostic and therapeutic laparoscopic adhesiolysis

R.M. Navaratham, S. Banerjee, C. Kelly and P.J. Macdonald
Departments of Surgery, Ealing, Northwick Park & St Marks Hospitals, Middlesex, UK. Correspondence to Mr R.M. Navaratham, Department of Surgery, Ealing Hospital, Middlesex, UK

Aim: To assess the role of diagnostic laparoscopy and therapeutic adhesiolysis in the management of right iliac fossa (RIF) pain, post appendicectomy.

Materials and methods: Eleven patients (9 females, 2 males, age range 18–45) presented over a 12 month period, with unremitting RIF pain. Each had previously undergone conventional open appendicectomy, for appendicitis, over a period of three months to 10 years. There was no clinical or radiological evidence of acute obstruction in any patient. All were managed conservatively initially. Abdominal and pelvic ultrasound were performed on all patients and contrast studies of the small and large bowel, where appropriate. Symptomatic relapse resulted in diagnostic laparoscopy and laparoscopic adhesiolysis being successfully performed on each patient.

Results: At laparoscopy no alternative cause for pain was identified, barring postoperative adhesions. Mean operative time for each procedure was 44 minutes. Postoperatively, analgesic requirements and symptoms were markedly reduced on visual analogue scales. Mean discharge time was 48 hours. There was no associated morbidity and no reattendance (follow up 7 months).

Conclusions: The concept of diagnostic laparoscopy and therapeutic adhesiolysis is attractive and offers all the advantages of minimally invasive surgery. Its role has been documented in the management of chronic pelvic pain and small bowel obstruction, however, it has not been formally documented in the management of post appendicectomy pain, secondary to intra abdominal adhesions. The success encountered in this short series, suggests that this is the tool of choice for the management of this condition.

Major postoperative complications and conversion causes in laparoscopic cholecystectomy for acute cholecystitis

A.E. Nicolau, I. Licà, R. Mehic, A. Spàtaru and G. Ionescu
Surgical Department, Emergency Hospital Bucharest,
8 Floreasca Avenue, 71406 Bucharest, Romania

Introduction: The aim of our retrospective study is to analyse the causes for conversions and major postoperative complications that appeared in laparoscopic cholecystectomy (LC) for acute cholecystitis (AC) and their influence on the length of stay.

Methods and materials: We have analysed only the cases for which beside the physical examination, laboratory tests and macroscopic aspect, the diagnosis of AC was confirmed by a pathology examination.

Results: Between December 1993–November 1997, we performed 192 LC for AC. Out of these patients 50 were men and 142 women; the mean age was 53·6 years (28–81). Severe forms of AC were: gallbladder empyema 40 patients, gangrene 39 patients, strong fibrous inflammatory adhesions (SFIA) around the cholecyst 22 patients. Of all the patients, 126 were operated on within the first 24 hours from admission (65·6 per cent). Conversion was necessary for 13 patients (6·7 per cent): 9 conversions for security reasons due to unclear anatomy (eight patients with AC and SFIA) and for one patient due to cystic artery lesion; 4 necessity conversions due to the presence of stones in the common bile duct. Fourteen patients (7·02 per cent) developed 20 major postoperative complications (10·41 per cent); in this group one patient died. The complications were: infectious 5 (wound infection), haemorrhagic 3, biliary 5 (postoperative fistula 1, bile leak 1, biliary subhepatic collection 3), incisional hernia 1, duodenal fistula 1, acute pancreatitis 1, cardiopulmonary complications 4. Four patients were operated on again: three by laparotomy and one by laparoscopy. Six patients had an AC with SFIA. Mean hospital stay for LC without major complications was of 3·6 days (3–6 days). For the patients for which conversion was performed, the mean hospital stay was of 8·9 days (5–20 days) and for those with major postoperative complications 13 days (3–33 days). For those patients with AC and SFIA, the mean hospital stay was of 7·1 days (5–10 days) if conversion was performed and of 14·5 days (3–30 days) if they had major complications.

Conclusions: The rate of postoperative complications for LC for AC is acceptable compared with existing data in the literature. Once the surgeon accumulates experience, these results can be improved. In the extremely difficult cases with unclear anatomy and especially for AC with SFIA, early conversion is beneficial for the patient and the surgeon, depending on her/his experience.

Our experiences obtained in the course of performing laparoscopic cholecystectomy (LC) in acute cholecystitis

Gy. Orgován, L. Fekete, G.C. Kovács, B. Bakity and
Z. Záborszky *Surgical Department, Central Military Hospital,*
Róbert Károly krt. 44, Budapest H-1134, Hungary

Our Department has been accomplishing laparoscopic cholecystectomy since April 1992. One thousand three hundred patients have been treated for cholecystolithiasis till the 31st of December 1997. 93 per cent of the patients were submitted to laparoscopic cholecystectomy and 7 per cent of the patients were operated in the 'open' way. The operative mortality was 0·7 per cent among patients submitted to LC and 0 per cent among those who were operated in the traditional way.

According to the general belief the acute cholecystitis is considered even today to be a relative contraindication of LC. In the period mentioned above there were 104 patients (8 per cent) in our department who were submitted to LC owing to acute cholecystitis. Signs of inflammation without previous clinical symptoms were found in 40 per cent of elective operations. In case of acute cholecystitis proved preoperatively operative interventions were preceded by a 2–4 day long antibiotic treatment, however in subacute inflammation opus had to be postponed.

In summary, our aim is to compare our results gained during applying LC with the results of the previous 'traditional' method of operations in acute cholecystitis, furthermore we are studying the preoperative examinations in connection with the operative findings and also the ways of avoiding complications.

Our opinion is that LC is worth choosing even in acute cases and not only the operative encumbrance is less for the patients but also the probability of postoperative complications is similar.

Is laparoscopic cholecystectomy with laparolift technique less invasive than open and pneumoperitoneum method?

J. Piłat, J. Bicki, S. Rudzki and M. Jesipowicz *First Department of General and Transplant Surgery of Medical University of Lublin, 8 Jaczewskiego Street, Lublin, Poland*

Surgical treatment is always connected with changes in homeostasis and tissue damage. The gold standard in gallstone treatment is cholecystectomy. In our work we have compared hormonal and inflammatory markers after three types of cholecystectomy: open, laparoscopy with pneumoperitoneum (12 mmHg) and gasless laparoscopy with laparolift (Origin) technique. These changes may have profound effects on metabolic and renal homeostasis, circulatory haemodynamics, immune competence and gastrointestinal physiology. It has some effects on patients' behaviour after surgery. Studies were performed on patients undergoing elective cholecystectomy. Patients were divided into three groups: open cholecystectomy 11 patients, laparoscopic with pneumoperitoneum 10 patients and with laparolift 14 patients. We examined levels of three catecholamines: adrenaline, noradrenaline and dopamine using HPLC-ECLD method, IL-6 and cortisol with immuno-enzymatic method and CRP with immunoturbidymetric method in patients' serum. Samples of catecholamines were taken before procedure, after anaesthesia but before surgical procedure half an hour after operation beginning, 2 and 24 hours after the end of procedure. Blood samples for IL-6 and cortisol were taken before operation, 6 and 24 hours after operation and for CRP before, 24 and 72 hours after operation. After our study we can conclude that hormonal response to surgical trauma after open procedure is higher than after two laparoscopic techniques. We have found no differences in two laparoscopic techniques in hormonal response. In laparoscopic technique with laparolift levels of catecholamine returns to levels before operation earlier than in open and laparoscopic with pneumoperitoneum method. Inflammatory answer is higher after open procedure than after both laparoscopic methods. We have found no differences after two laparoscopic methods.

Gasless laparoscopic surgery. Our perspectives based on an experience of more than 500 successive cases

M.J. Queiroz-Medeiros, J. Raposo d'Almeida, A. Menezes Silva,
H. Vasconcelos Dias, J.L. Nunes and C. Balhana *Dept. of*
Surgery, Hospital de Pulido Valente, New University of Lisbon,
Alameda das Linhas de Torres, 117-1750 Lisboa, Portugal

We perform gasless laparoscopic surgery routinely since 1994. Under this technique 515 successive operations have been carried out between January 1994 and July 1997, including cholecystectomies (one case with choledocolithotomy), Nissen fundoplication, vagotomies (posterior vagotomy and anterior seromiotomy or anterior linear gastrectomy, and truncal vagotomia and antrectomy), gastrenterostomy, treatment of hepatic cysts including bloc-resection of hydatid disease, splenectomy, cholectomies and gynecologic surgery (hysterectomies, anexectomies).

Results: Mean duration of surgery and hospital stay are similar (or better) to operations performed with CO_2 pneumoperitoneum. The conversion rate to open surgery was 3·3 per cent. Indications are referred. Major complications have been found only in seven cases consisting of duodenal injury, cystic duct leak, residual common bile duct stone, bile duct injury – diagnosed at the time of surgery and managed by primary repair over a

T tube) – duodenal stump leak and ureteral injury. A second operation was performed in five patients (1 per cent) for cystic duct leak, haemorrhage, duodenal perforation, duodenal leak and ureteral injury. There was postoperative shoulder pain in three cases.

Advantages of the procedure: an airtight pneumoperitoneum is not required; therefore we only use valveless trocars, conventional surgical instruments can be safely and routinely introduced, high volume irrigation is easily accomplished and continuous suction can be applied to the operative site without altering the exposure. The main problem is the difficult exposure in some cases, particularly in obese patients, which is solved by using an additional retractor.

Conclusion: Gasless laparoscopy is technically feasible, safe and effective, even in unselected patients, and it is a good route of choice for many different operations which can be routinely indicated for several reasons: it involves low complication and conversion rates, short duration of surgery, early postoperative discharge, and good functional and cosmetic results; it provides a good exposure and avoids the operative risk related to disturbances inherent to pneumoperitoneum; it makes postoperative should pain a rare complaint; it allows the use of conventional instruments, thus reducing the need of the disposable ones and making surgery easier and more cost-effective.

Endoscoic polipectomy as a preventive treatment of large intestine cancer

J. Rdes, M. Rudzki, K. Sosada, W. Żurawiński, P. Szenk and M. Martula *From the III Clinic of General Surgery, Silesian School of Medicine, Żeromskiego 7, 41-902 Bytom, Poland*

A considerable increase in the number of large intestine cancers has been reported lately. Most of the cancers of this type are situated in polyps.

In the years 1988–1997 endoscopic polipectomy was performed in 184 patients, aged 23 to 80 years. The size of the removed polyps varied from 0·3 to 2·5 cm. There were 134 cases of a single polyp and 50 cases of numerous polyps (2–9 polyps per patient). Polyps were removed by means of diathermic loop or 'warm biopsy'. Macroscopic examination revealed benign lesions of adenomatous or tubular type in 176 patients, and adenocarcinomas in the remaining eight cases. All malignant polyps were larger than 1 cm. As the infiltration of the peducle was noted the surgery was performed in all eight cases. Postpolipectomic complications were recorded in three patients (1·6 per cent): two cases of arterial haemorrhage from the peducle of the removed polyps and one case of the simgoid perforation, which took place 26 hours after the surgery. All patients operated due to adenocarcinoma are regularly examined by means of colonoscopy in diagnostic cycles of 6, 12, 24 and 36 months. So far no cases of recidivation have been reported.

Conclusions:

1. Endoscopic polypectomy enables avoiding surgery in the case of benign lesion.
2. Early detection and removal of a polyp protects from its changing into a malignant one.

Postoperative pulmonary function after laparoscopic and open cholecystectomy

D. Şeker, G. Necipoğlu and A. Özkardeş *Naci Çakır Mah. 13. sok. Gündüzler sitesi A-Blok D:2 İlker, Ankara, Turkey*

Open cholecystectomy causes changes in pulmonary functions showing a restrictive pattern which can be related to respiratory complications of hypoxemia and atelectasis. Eighteen patients undergoing open cholecystectomy and 20 patients undergoing laparoscopic cholecystectomy, all in ASA I group, were prospectively evaluated by pulmonary function tests. Functional residual capacity (FRC), forced vital capacity (FVC), forced expiratory volume in 1 second (FEV1) and forced expiratory flow (FEF 25 to 75 per cent) were measured before operation and on the morning after surgery to determine if laparoscopic cholecystectomy results in less respiratory impairment. The results revealed significant but less decreases in laparoscopic cholecystectomy (6, 23, 20, and 23 per cent respectively) than after open cholecystectomy (21, 36, 32, and 36 per cent respectively).

We conclude that laparoscopic cholecystectomy provides less impairment in pulmonary functions than open cholecystectomy. That may account for the reduced rate of respiratory complications after laparoscopic cholecystectomy.

Foreign body removal – a problem for endoscopy rather than for surgery

K. Sosada, J. Hudyka, W. Żurawiński, A. Stańkowski, J. Rdes and M. Rudzki *From the III Clinic of General Surgery, Silesian School of Medicine, Zeromskiego 7, 41-902 Bytom, Poland*

Foreign bodies are in the majority of cases the results of self-injury of prisoners. Most of the foreign bodies are metal or wooden cross-like, self-expanded structures (two wires bound in the middle with a piece of elastic) with sharp ends. When swallowed, the objects create the risk of oesophagus wall perforation and the injury of big vessels. Most of the patients operated on due to foreign bodies in the alimentary canal undergo this type of intervention repeatedly. In the years 1994–1997, 39 attempts were done to remove foreign bodies from the oesophagus by means of endoscopy. The patients were men, aged 17–35 years. In each case a contrast X-ray of the oesophagus was done before the endoscopy to exclude the wall perforation. In 16 patients the cross-like foreign bodies expanded and stacked in the second isthmus of oesophagus. In 23 cases they were held up over the cardial part of the oesophagus. Thirty-three endoscopic interventions were performed in local anaesthesia, 16 in general anaesthesia. Foreign bodies were satisfactorily removed from the oesophagus in 30 cases. A typical intervention started with cutting the elastic that bound two arms of the cross. Then each arm of the cross was removed separately with the use of diathermic loop. In eight cases the arms were removed from the inflammatory infiltration of the oesophagus wall and no cases of wall perforation were noted. In nine patients an attempt to remove a foreign body from the oesophagus was unsatisfactory due to technical difficulties. Foreign bodies were removed surgically by means of thoracotomy (2 cases), gastrotomy (3 cases), and through the cervical access (4 cases). Before gastrotomy the foreign body was endoscopically introduced into the stomach. Endoscopic removal of foreign bodies from oesophagus is a very difficult procedure. It is especially recommended for those patients who swallow some foreign bodies repeatedly. If performed satisfactorily, the method lets us avoid an extensive surgery burdened with the risk of intra- and postoperative complications. The endoscopic intervention should be performed by a surgeon-endoscopist, who, if necessary, could convert to surgery.

Laparoscopic Heller myotomy and fundoplication for achalasia

J. Vazquez Echarri, J.M. Romeo, C. Montes, J. Martin Benito, M.L. Ares, N. Herrera, A. Marinelli, A. Garcia Alvarez, D. Lacasa, M. Uribazo and J.L. Martinez Veiga *Serv. de Cirugía General y Digestiva, Hospital 'Severo Ochoa', Avd. de Orellana s/n. Leganes, 28911 Madrid, Spain*

Introduction: In spite of the fact that pneumatic dilation of the cardia in achalasia offers some acceptable results not exempt of risks, dysphagia, although diminished, usually reappears during the first months. So, laparoscopic Heller myotomy associated with a Dor fundoplication, with or without previous dilation, is in our opinion the definitive treatment for achalasia.

Patients and methods: Between January 1995 and July 1997, 8 consecutive patients were treated. Three of them had a previous pneumatic dilation only temporally successful. The preoperative manometries showing a LESP from 36 to 12 mmHg and aperistalsis supported the diagnosis of typical achalasia with a case of vigorous type. The surgical technique was similar in all patients but nowadays the hiatus dissection is limited, preserving the posterior attachment. Five trocars of 10 mm were used. There were dissected at least 7 cm of oesophagus, identifying and preserving later on while the myotomy the anterior vagus. The myotomy was carried out with scissors and electrocoagulation, maintaining an intraeoesophageal bugie of 40F, beginning 2 cm below the gastroesophageal junction. We used the cardial artery as anatomical reference. The myotomy is prolonged upwards in about 6 cm testing by intraoperative endoscopy its completion and the absence of perforation We associated a partial fundoplication Dor type to avoid the gastroesophageal reflux In a case, with previous balloon dilation, a microperforation was identified and sutured without postoperative complications. Mean operative time was 130 min The postoperative stay was between three and six days

Results: Only four cases have a follow-up longer than one year All cases but one are asymptomatic without dysphagia or gastroesophageal reflux A case has deglutory problems secondary to the oesophageal aperistalsis with a LESP of 3·5 mm Hg and a correct Heller myotomy in endoscopy

Laparoscopic splenectomy

J. Vazquez Echarri, J.M. Romeo, R. Llorente, A. Marinelli, C. Montes, M.L. Ares, J. Martin Benito, P. Fdez Isabel, S. Piñero, E. Gonzalez and J.L. Martínez Veiga *Serv. de Cirugía General y Digestiva, Hospital 'Severo Ochoa', Avd. de Orellana s/n. Leganes, 28911 Madrid, Spain*

Introduction: Nowadays autoimmune hereditary anaemias (AIHA) and idiopathic thrombocytopenic purpura (ITP) with poor response to steroid treatment are the more frequent indications for splenectomy Laparoscopic splenectomy offers the advantage of minimal invasion and seems to be an attractive alternative.

Patients and methods: Between September 1994 and June 1997, 18 consecutive patients, 17 female, with ages between 12 and 71 years underwent laparoscopic splenectomy Indications for splenectomy were medication resistant ITP in 11 cases, AIHA in four, spherocytosis in one, thrombotic thrombocytopenic purpura (TTP) in one and splenic cyst In patients with ITP the platelet count ranged between 9000 and 3600 mm^3 In all cases high-dose immunoglobulins and pneumococcal vaccine were given before the operation. After the administration of high-dose immunoglobulins the platelet count raised, and ranged between 60 000 and 140 000 mm^3. Preoperative sonography showed a mean splenic length of 12 cm and no accessory spleens were detected. The surgical technique was always similar, using four ports as described in other communication

Results: The length of the operation ranged between 135 and 210 min Laparoscopic splenectomy was successfully performed in 17 cases One conversion was necessary because uncontrollable but non-important bleeding (the second case) In one case was necessary to reoperate the patient in the postoperative period. In one case, injury to a sizeable vessel was controlled by laparoscopy. Accessory spleens were searched for systematically It was found in one patient (not showed previously in sonography) and removed successfully In 15 cases the postoperative course was uneventful One patient had a small subphrenic collection resolved in 7 days without drainage The postoperative stay ranged between 2 and 9 days (median of 3 days) In the patients with ITP the postoperative mean platelet count was 230 000 mm^3 (range 125 000–430 000 mm^3)

Comments: The laparoscopic approach has demonstrated to be as effective and safe as the open, also to localize ectopic spleens.

Diagnostic and operative laparoscopy in diagnosis and treatment of selected acute abdominal diseases

W. Waśkiewicz, M. Szczepkowski and K. Górnicki *Surgical Department, Bielany Hospital, Ceglowska str. 80, 01-809 Warsaw, Poland*

Aim: Aim of the study was to evaluate how the laparoscopic technique may improve a diagnosis and enable a treatment of common acute abdominal diseases.

Material and methods: 157 patients (72 women and 85 men) qualified for laparotomy were laparoscopized. Appendicitis was suspected in 88 cases, in the rest (69 cases) – acute cholecystitis Mean age was 53 years Then we performed a laparoscopy and (if possible) a definite treatment was done.

Results: In the group suspected of appendicitis the accuracy of diagnosis was 75 per cent. Other findings were. cystis ovarii ruptum (20·4 per cent), pyosalpings (3 5 per cent), and tumour coeci (1 1 per cent). Mean appendectomy time was 42±21 min Conversion rate during appendectomy was 9 1 per cent (6 cases) Conversions were performed because of hard inflammation of caecum, anatomical doubts and some technical troubles. Complications of laparoscopic appendenctomy: perforation rectum due to diathermy (1 case), intraabdominal collection (2 cases). No wound infection was noted Mean hospital stay was 4±3 days In the group suspected of cholecystitis the accuracy of the diagnosis was 98·6 per cent In one case (1 4 per cent) perforation of duodenal ulcer was found Mean cholecystectomy time was 66 4±28 min Conversion rate during cholecystectomy was 11 8 per cent (8 cases) Main reasons were anatomical doubts – 4 cases, inflammatory inflammation – 2 cases, bleeding from hepatic lodge – 2 cases. Complications noted wound infection (1 case), biliar peritonitis (1 case), duodenal perforation (1 case), intraabdominal abscess (2 cases). Mean hospital stay was 4 5±3·2 days

Conclusion: Laparoscopy and laparoscopic operative technique may be very useful in many – especially difficult – cases of local peritonitis. In a few cases this technique enables a final treatment of the disease

Laparoscopic cholecystectomy (LCh) in the cirrhotic patients

T. Wróblewski, J. Pawlak, P. Małkowski, M. Krawczyk, B. Michałowicz, P Paczkowski and A. Karwowski *Dept of General Surgery and Liver Diseases, The Medical University of Warsaw, Poland*

Purpose: Liver cirrhosis is a serious surgical risk factor because of the patients' general condition and certain technical difficulties due to rich collateral circulation and bleeding tendency Simple cholecystectomy might become a serious surgical problem

Methods: Sixteen cirrhotic patients underwent LCh because of the gallstone disease According to the Child–Pugh classification 7 patients were in A group, 8 in B and 1 in C (waiting for OLT) Each patient was prepared with special care to assess his liver function and bleeding tendency profile In five patients with the sonographic evidence of the CBD stones, LCh was preceded by ERCP and in three cases the stones were found and removed The Child C patient (with CBD stones and cholecystitis) was prepared with 4 units of plasma transfusion prior to ERCP and next 4 units before LCh in order to prevent coagulation disorders. In 11 cases LCh was an elective procedure, in five cases a delayed emergency procedure.

Results: LCh was performed safely and successfully in all patients. In three cases a moderate bleeding from the gallbladder lodge was effectively controlled by spongogel placement and 2 units of plasma transfusion Drainage of the gallbladder lodge were done in all the patients The average time of the intervention was longer than that in non-cirrhotic patients. No case of postoperative bleeding, liver failure or other complications was observed The average hospitalization period was 5 days (3–7 days)

Conclusions: Our experience suggests that LCh in the cirrhotic patients is an effective and safe alternative to open cholecystectomy

Endoscopic polypectomy of the lower part of gastrointestinal tract in own material

W. Zegarski, S. Dąbrowiecki and W. Szczęsny *The Ludwik Rydygier Medical University in Bydgoszcz, Department of General and Vascular Surgery, ul. M. Skłodowskiej-Curie 8, 85-094 Bydgoszcz, Poland*

The data present own experiences and analysis of colonoscopic examinations of the lower part of gastrointestinal tract with special consideration of endoscopic polypectomy. In the period of time from 1984 to 1997, 1512 colonoscopic examinations have been done On 344 cases endoscopic polypectomy have been done. The polypectomies in 90 per cent were performed in outpatients department.

Patients were prepared with special kind of diet (for 3 days they have had only jelly and drinks)

All removed polyps were histopathologically examined. In two examined polyps the carcinoma diagnosis was established. We experienced 5 complications – 4 bleedings and 1 perforation. All patients are well and disease free 3 and 6 months after polypectomy.

In our opinion this model seems to be an easy and safe method of colon polyps treatment. Simultaneously it is an efficient method in prevention of colon cancer.

Metabolic and immune response to operative trauma during laparoscopic and open cholecystectomy

W. Żurawiński, K. Sosada, J. Rdes, M. Rudzki, W. Mikusek and M. Martula *III Klinika Chirurgii Ogólnej, Śląska Akademia Medyczna w Katowicach, ul. Żeromskiego 7, 41-902 Bytom, Poland*

The aim of the study is the comparison of metabolic changes and the concentration of acute phase protein changes caused by the intraoperative trauma during laparoscopic cholecystectomy (lch) and open cholecystectomy (lch). The examination was carried out in 90 patients having an operative treatment because of non-complicated cholecystolithiasis between 1994 and 1997. The laparoscopic method was used in 60 patients including 40 women and 20 men at the average age of 47. Open cholecystectomy was carried out in 30 patients, including 22 women and 8 men at the average of 42. The concentration of C-reactive protein (CRP), component C3 of the complement, immunoglobulins G, A, M, fibrogen, glucose, sodium, kalium and leucocyte count were determined in blood sampled 24 hours before the operation and 4, 24, 48, 72 and 96 hours after the operation. The dynamics and the range of temperature changes of the patients bodies in the perioperative period were examined as well. The highest concentration of CRP was recorded in both groups 48 hours after the operation. After lch concentration of CRP increased four times and after och 14 times. On the second and third day after the operation concentration of CRP gradually decreased. Statistically significant changes in C3 concentration were not found in both groups of examined patients. The observed decrease in immunoglobulin concentration was similar after lch and och. The increase in fibrinogen concentration proceeded within the normal range and on the first day equalled 45 per cent of the perioperative value for lch and 60 per cent for och. On the operation day the increase in glucose concentration of 0·5 mmol/l, leucocyte count of 1·8 g/l, sodium concentration of 6·9 mmol/l, and the decrease in kalium concentration of 0·4 mmol/l on average were observed after lch. The increase in glucose concentration of 1·9 mmol/l, leucocyte count of 5·3 g/l, sodium concentration of 6·4 mmol/l and the decrease in kalium of 0·6 mmol/l were observed after och on the operative day. Lesser disturbances in aggressive metabolism and lesser concentration of acute phase proteins are observed after lch. It is related to the lesser intraoperative trauma in comparison to och. The numerous clinical advantages result from lesser intra- and postoperative stress.

Routine compared with non-scheduled follow-up of patients with 'curative' surgery for colorectal cancer

J.P. Arnaud, R. Bergamaschi, Ch. Cervi and J.J. Tuech *CHU Angers, Department of Visceral Surgery, 4 rue Larrey, Angers 49100, France*

Background: The main rationale for follow-up of colorectal cancer patients resected for 'cure' is that early detection and treatment of recurrence and metachronous disease should result in improved survival. Our purpose was to assess in a prospective fashion the impact on survival of a follow-up program vs that of undergoing non-scheduled visits.

Methods: From 1980 through 1993, a prospective study was carried out on 800 patients with colorectal adenocarcinoma radically resected with no evidence of synchronous cancers of the colon and rectum or in other organs, of whom 322 patients were to attend a 5 year follow-up, and 478 patients were free to make non-scheduled visits on account of symptoms.

Results: Asymptomatic recurrence was found at follow-up in 92 (28 per cent) of 322 patients, whereas 175 (36 per cent) of 478 patients had a symptomatic recurrence detected at a non-scheduled visit. Diagnosis of resectable recurrence was established within a median time of 21·5 months. Surgical resection of recurrence was performed in 30 (32 per cent) of 92 and in 13 (7 per cent) of 175 patients (32 vs 7 per cent; $P<0{\cdot}001$). Resection was curative in 13 (14 per cent) of 92 and in two (1 per cent) of 175. Five year survival of resected recurrence as 10 per cent in 30 of 92 patients and 0·8 per cent in 13 of 175 (10 vs: $P<0{\cdot}01$). Two patients are alive with no evidence of disease or two (2 per cent) of 92. Metachronous colorectal lesions were treated for cure in 63 (19·5 per cent) of 322 patients. The effectiveness of scheduled follow-up was 4 per cent (13 of 322 patients).

Conclusion: These results underline the rationale for a follow-up programme in early detection and surgical treatment of recurrent disease in patients operated on for colorectal cancer.

111-In labelled antibodies in the detection of colorectal carcinomas

V. Artiko, V. Obradović, B. Davidović, N. Petrović, M. Petrović, Z. Krivokapić, D. Kecmanović, G. Adanja and R. Rebić
Institute for Nuclear Medicine, Clinical Center of Serbia, Višegradska 26, 11 000 Beograd, Yugoslavia

Oncoscint CR 103 is an immunoglobulin which recognizes a tumour-associated glycoprotein (TAG-72) expressed in several cancers of epithelial origin, including colonic adenocarcinomas. The aim of the study is detection of the recurrences and metastases of colorectal carcinomas using 111-In labelled antibodies B72.3.

Fourteen patients have been examined (13 with adenocarcinomas of caecum, colon and rectum and one with squamocellular colonic carcinoma) from 4 months till 2 years after surgery, two of them after 2 months after the end of radiotherapy. Radiochemical purity of the radiopharmaceutical was over 97 per cent. Planar anterior, lateral and posterior scintigrams of thorax, abdomen and pelvis are done after 10 min, 24, 72 and 96 h after i.v. injection of Oncoscint CR-103, containing monoclonal antibodies B72.3 labelled with 150 MBq 111-In while tomographic scintigrams of the pelvis are done after 72 h.

In 12 patients recurrences of carcinomas (5–12 cm), in six recurrences with liver metastasis, and in two only liver metastases were detected and confirmed by surgery. Planar immunoscintigraphy was positive in 8/8 patients with liver metastases and 9/14 patients with recurrences while in 5/14 recurrences were detected only by tomography. US patients with recurrences, while MRI in one. In three patients with recurrences, CEA was not increased. In four patients intensive accumulation of labelled antibodies was observed in colostomas, in one with granuloma, as well as in one with recurrence of squamocellulare carcinoma.

We can conclude that with tomography, we can access better distinction of tumour in comparison to other structures and estimation of its size. Other imaging methods (CT, US) have advantage in detection of liver metastases, while immunoscintigraphy is more specific for the assessment of malignant abdominal tumours and extrahepatic metastases. The first results point out that Oncoscint CR-103 can be useful in diagnosis of recurrences and metastases of colorectal carcinoma, viability assessment after radiotherapy and in the choice of the adequate surgical treatment in dependence of the spread of the disease.

Changes in colorectal surgery at our department during a 10 year period

B. Bakity, G.C. Kovács, Gy. Orgován, L. Fekete and Z. Záborszky *Surgical Department, Central Military Hospital, Róbert Károly krt. 44, Budapest H-1134, Hungary*

We have performed 612 colorectal operations during the investigation period of 1988–1997. This 10 yerar period was divided into two 5-year periods (1988–1992 and 1993–1997) and we have compared mortality rates, operation types and suturing technique in acute and elective surgery.

In acute surgery we have found a decrease in the number of 2 or 3-phase surgical interventions and a decrease in mortality rates (24 per cent during the first period and 15 per cent during the second one) due to tendencies to primary definitive care (extended resections, intraoperative bowel irrigation).

In elective surgery of mid and lower third rectal tumours the number of sphincter saving operations increased, staplers were used more frequently (the ratio of stapler and hand made sutures in the first period was 2/3 and 4/1 in the second one) and suture insufficiency occurred at a lower rate during the second period, beside similar mortality rates (1·3 per cent).

Prediction of complications after colorectal surgery using gastric tonometry and cytokines

F.G. Bergin, P.A. Mallinder, P. Royle, L. Garbett and D.J. Leaper
Professional Unit of Surgery, North Tees General Hospital, Stockton-on-Tees, Cleveland, UK

Aim: We have estimated the value of gastric tonometry and IL6 and TNFα in prediction of complications after elective colorectal surgery in a prospective randomized study involving propofol and epidural anaesthesia.

Materials and methods: A significant advantage has already been shown in patients having an epidural, being associated with shorter operations (median 126, range 60–280 mins vs 180, range 86–240; $P<0{\cdot}01$), less blood loss (median 710, range 200–2235 ml vs 1325, range 250–2725; $P<0{\cdot}05$), better pain relief (83 per cent vs 37 per cent; $P<0{\cdot}02$) and a tendency to return home earlier.

Results: Only IL6 levels predicted postoperative complications (day 1; 200, range 72–600 pg/ml vs no complications 97, range 0–595; $P<0{\cdot}002$). No similar association was found with TNFα. There was a fall of gastric mucosal pH during operations (median fall of pH 0·08) but this had no relation to type of anaesthesia, blood loss, length of operation or the development of postoperative complications.

Conclusion: Plasma levels of IL6 can predict surgical complications after elective colorectal surgery but gastric tonometry was unhelpful, which probably reflects good intraoperative anaesthetic practice.

A simple method to determine the length of bowel resection in the presence of colonic ischaemia

A. Bernardes, S. Monte-Arroio and J. Patrício *Coimbra University Hospital, Surgery I and Experimental Investigative Laboratory, Serviço de Cirurgia I, Hospitais de Universidade de Coimbra, Av Bissaya Barreto e Praceta Prof Mota Pinto, 3049 Coimbra Codex, Portugal*

It is well known that necrosis due to colonic ischaemia of the mucosa is greater than of the serosa. The surgeon must always resect a piece whose length is greater than the area of identifiable necrosis but it is always difficult to determine the exact resection margins.

Ojective: Obtain a simple and practical method to determine the length of bowel resection when there is a transmural necrosis of the colon.
Material and methods: Organs from 46 human cadavers were used. The marginal arterial arcade (marg. arc.) was resected: 5 cm in 17 cases (group I); 8 cm in 17 cases (group II); 12 cm in 12 cases (group III). The organs were then injected via the *arteria mesenterica inferior* and studied using the following techniques: diaphanization (42); microangiography (6/42); scanning electronic microscopy of corrosion casts (4).
Results: The colon in the site of the devascularization presents: 1) *Group I* – in 73·3 per cent of the cases the serosa shows a decrease of its colour with an average length of 1·7±0·18 cm. The area of discoloration of the mucosa is 29·4 per cent or 88·2 per cent greater than the discoloration of serosa at the free colonic and mesocolonic borders respectively; 2) *Group II* – in 53·3 per cent of the cases the serosa shows a discoloration with 2·8±0·37 cm. The area of the discoloration of the mucosa is 28.6 per cent or 82·1 per cent greater than the discoloration of serosa at the free colonic and mesocolonic borders respectively; 3) *Group III* – in 100 per cent of the cases the serosa shows a disocloration with 5·3±0·43 cm. The area of the discoloration of the mucosa is 39·6 per cent or 83·0 per cent greater than the discoloration of serosa at the free colonic and mesocolonic borders respectively.

To the above percentages we added the number 1 (i.e. 1·294; 1·882; etc.) and then rounded off to the decimal, obtaining in this manner values 1·3–1·4 and 1·8–1·9. We classified these numbers *minimum* and *maximum* quantification indexes of the mucosal ischaemia, respectively. The diaphanization, microangiography and scanning electronic microscopy showed that the discolorations represent a proportional decrease of the product inside the vessels.
Conclusions: In cadavers, the devascularization seems to reveal that the ischaemia of the mucosa at the level of the free colonic border is 1·3 to 1·4 times greater than what is observed at the surface of the bowel, and increase to 1·8 to 1·9 at the level of the colonic mesocolonic border. We propose to name those values by *minimum* and *maximum* quantification indexes of the mucosal ischaemia, respectively. These simple and practical numbers can help surgeons evaluate the length of the mucosal lesion. In order to determine bowel resection margins the surgeon needs only to multiply the index value by the area of ischaemic visible on the serosa.

Multiple colon tumours. Diagnosis and follow-up of 600 patients with colorectal carcinoma

J.C. Bernal-Sprekelsen, J. López, F. Peiró, F. Cárdenas, F. Puchades, J. García-Romero and R. Trullenque *Hospital General Universitario de Valencia, Servicio de Cirugía General, Spain*

Aim: Failure to diagnose synchronous tumours leads to error in patient treatment and prognosis. The existence of metachronous tumours requires strict patient follow-up to ensure early identification of the second tumour. The present study evaluates the results obtained with a structured protocol for diagnosis and follow-up of multiple colorectal carcinoma.
Materials and methods: A structured procedure was used to follow for 6 years (from 1991 to 1997) a group of 15 patients (2·5 per cent) with multiple colorectal tumours (7 synchronous and 8 metachronous) of a series of 600 colorectal neoplasms. Synchronous tumours were those which appeared within 6 months after the initial diagnosis, with mucosa appearing healthy during the interval between detection of the two tumours. Metachronous tumours were those found later than 6 months after diagnosis of the first tumour. Nine patients were men and six were women with a mean age of 67 years (range: 45–83). The disease was staged according to the system of Astler-Coller. Postoperative examinations consisted of colonoscopy one month after surgery if the preoperative examination was incomplete, serum carcinoembryogenic antigen (CEA) every three months, and complete annual check-up (clinical examination, laboratory tests, chest X-rays, ultrasound or tomographic liver study, CEA, colonoscopy and pelvic tomographic studies in rectal cancer).
Results: Six synchronous tumours were diagnosed preoperatively and one intraoperative. Of the eight metachronous tumours, seven strictly adhered to the follow-up protocol, as a result of which the second tumour was detected at an early stage. The remaining case involved no follow-up, and the second tumour was diagnosed in an advanced stage as a result of bowel obstruction. The left colon was predominantly involved; polyps were detected in 10 cases while two patients had three malignancies detected by histopathological study.
Comments: We emphasize the need for a full evaluation of the colon in all patients with colorectal carcinoma. In the case of incomplete preoperative evaluation, intraoperative colonoscopy is to be considered; if this is not feasible it should be performed one month after surgery. A structured follow-up procedure permits early detection of these tumours, thereby improving patient prognosis.

The methods of surgical treatment of total large bowel obstruction

A. Boguševičius and D. Pavalkis *I Surgical Clinic, Kaunas Medical Academy, Eivenių 2, 3007 Kaunas, Lithuania*

Aim: Aim of this study was to evaluate effectiveness of the on-table large bowel antegrade irrigation and Hartmann's procedure in totally obstructed left sided large bowel carcinoma.
Materials and methods: Data of the 60 patients were collected prospectively without randomization. Hartmann's procedure was performed in 49 patients, and irrigation and primary anastomosis in 11 patients. Irrigation was done as described by A.G. Radcliffe (1983).
Results: Two groups of the patients have shown no differences in age, sex, carcinoma TNM stage and morbidity and morality postoperative rate. Mortality was 20·4 per cent (10 patients) in Hartmann's operation group to compare with 18·2 per cent (two patients) in irrigation group. There were no specific intraoperative complications which could be attributed to irrigation, but two cases of anastomatic leakage were recorded. One case was treated conservatively, but another was reoperated and died of septic complications. In irrigation group, of course, there were no colostomy complications, in the other group 12 patients were noted with complications. Only statistically significant difference was found in duration of the hospitalization. In Hartmann's op. group it was 24·1±15·3 days, to compare with 16·6±8·0 days in irrigation and primary anastomosis group ($P<0·05$).
Conclusion: It was concluded, that on-table large bowel irrigation is convenient, safe and economically reasonable procedure in treatment of the obstructing left sided carcinomia of the large bowel. Nevertheless, it is related with high morbidity and mortality. The preoperative recanalization of the tumour can be the way of solution of this problem.

Respects of antibiotic therapy in elective surgery of colorectal carcinoma

J. Bóni, Z. Nábrádi, P. Tóth, I. Takács and P. Sápy *2nd Department of Surgery, University Medical School of Debrecen, Móricz Zs. str. 22, Debrecen 4004, Hungary*

Aim: Authors evaluate the results of the elective resections of the colon because of colorectal carcinoma between 1991 and 1997. The methods and the effectivity of the antibiotic profilactical therapy were also studied.
Patients and methods: In this period 488 operations were performed, 374 cases of them had elective operations (76·6 per cent). The patients mean age was 64·5 (26–94), male–female rate was 1·2:1. Before all of the interventions the patients had preoperative mechanical preparation of the colon. In the last 4 years cefetoxime, metronidazole antibiotic treatment was used as profilaxis. The surgical methods were the following: in 202 cases different types of resection of the colon (54 per cent), anterior rectum resection in 58 cases (15·5 per cent), abdominal perineal extirpation of the rectum in 57 cases (15·3 per cent), gastrointestinal bypass operation in 15 cases (4 per cent), definitive colostomy in 42 cases (11·2 per cent) were performed.
Results: The used antibiotical profylaxis treatment was effective, the rate of the insufficiency of the anastomoses was lower with 1·6 per cent, the suppuration was lower with 2·4 per cent than the former used antibiotics. The mortality in 30 days was also lower with 1·6 per cent than before. Comparing the simple and multiple doses of antibiotic therapy significant difference has not been found in the results of our operations.

Conclusion: On the base of our results the preoperative mechanical preparation of the colon together with the combination of cefetoxime, metronidazole antibiotic profilactical therapy is an effective treatment for the preparations of the patients.

Immunocytochemically detectable metallothioneins in chronic ulcerative colitis

M. Brüwer, K.W. Schmid*, N. Senninger, G. Winde and G. Schürmann *Departments of Surgery and *Pathology, University of Münster, Waldeyerstr. 1, 48149 Münster, Germany*

Introduction: Metallothioneins (MTs) are a set of low-molecular weight proteins with a high binding affinity for heavy metal ions. MTs have been shown to be potential scavengers of oxygen derived free radicals occurring during inflammatory processes Furthermore a possible cytoprotective role for circulating MTs has been demonstrated in chronic gastric ulceration
Aim: The aim of the present study was to investigate whether immunohistochemical MTs expression in ulcerative colitis (UC) is associated with the activity of disease and whether MTs have a cytoprotective role.
Materials and methods: MTs expression on routinely processesd colectomy specimens from 48 patients with UC was immunohistochemically demonstrated by means of the monoclonal anti-MT antibody E9. MTs expression was although examined in histologically normal uninflamed colonic mucosa of 10 patients who underwent colectomy for colon cancer
Results: In colon cancer specimens with normal appearing mucosa no MTs expression was observed In UC a strong MTs overexpression in intestinal epithelial cells was seen in 14/48 specimens and in a moderate in 9/48 without correlation to degree of inflammation. MTs overexpression was although found in fibromyoblastic spindle cells at the base of almost all ulcers observed.
Conclusions: MTs overexpression in fibromyoblastic spindle cells of ulcerative lesions indicate a possible protective role of MTs in the inflammatory process (binding protein for free radicals). On the other hand immunohistochemically MTs expression does not seem to be an indicator of disease activity in UC

Total proctocolectomy and ileoanal anostomosis with ileal J-pouch

A. Bulut, D. Şeker, Z. Ergul, O. Kaya, G. Osmanoğlu and İ. Baran *SSK Ankara Hospital, 3rd Clinic of General Surgery, Dışkapı, Ankara, Turkey*

Ileoanal anostomosis with ileal J-pouch that has been done with proctocolectomy operations prevents patients from the physical and psychological damages of permanent ileostomies

In between the years 1989 and 1997, total colectomy + mucosal proctectomy + ileoanal anostomosis with ileal J-pouch (with protecting loop ileostomy) operation had been performed to 18 patients with stapling technique in our clinic. Preoperative diagnosis of five patients (all are male and ages range between 31 and 58) was ulcerative colitis In 11 patients the preoperative diagnosis was poliposis coli (8 male, 3 female and ages range between 18 and 42). And two patients had familial poliposis (father and sister, ages 45–21) In two patients with poliposis coli, differentiated adenocarcinoma had been detected pathologically at postoperative period In all patients protecting ileostomy was closed 8 weeks after operation.

After the operations, in one patient anal structure and anostomotic leakage developed in early postoperative period, then leakage and stenosis were improved by reoperation In one patient anal incontinence developed postoperatively but this was improved with anal exercises by 2 months In one patient pouchitis had been developed and this problem was overcome with medical treatment (morbidity is 16 66 per cent) In one patient pouchitis had been developed and this patient died because of this complication at 10th postoperative day (mortality is 5·5 per cent) One patient died at postoperative 16th month because of biliary cirrhosis. All other patients are under follow-up and well by today. The mean defecation habit is 4–7 times a day 3 months after operation

We conclude that total proctocolectomy + ileoanal anostomosis with ileal J-pouch operation is a good procedure of choice to save the patient's comfort with acceptable ratios of morbidity and mortality.

Colon schwannoma. A exceptional case report

A. Caro, A.E. Hernandez, J.M. González, J.J. Ruiz, G.J. Vaquero, F. García and E. Del Amo *Departments of Surgery, 'San Pedro de Alcantara' Hospital, Alfredo Caro Mancilla, C/ Avda. Millán Astray S/N, Caceres 10003, Spain*

Introduction: Neurogenic tumours originate on peripheral nerves, where they may or may not be associated with Von Reckinghausen neurofibromatosis Although they are more frequently found on the acoustic nerve (acoustic neurilemoma), and only rarely found in the digestive system, there mostly in the duodenum, they are only exceptionally found in the colon.
Case report: This is the case of a 75-year-old female patient with a clinical history of asthenia, anorexia and slight weight loss High level of anaemia (5 9 g of haemoglobin and 19 per cent of haematocrit). In the study of this anaemia a colon repletion defect is observed in contrast enema; a colonoscope reveals an ulcerated mass 45 cm from the anal margin which biopsy reports as a schwannoma Surgical intervention follows, revealing a tumour of 6 cm in diameter occupying the sigmoid colon and ulcerating the mucosa. A sigmoidectomy is carried out, with mechanical anastomosis The definitive study from pathological anatomy reports a benign schwannoma with predominance of A-Antoni areas. Evolution is satisfactory with later tests giving normal results
Comments: Presence in the colon is exceptional, and international medical literature does not describe any such case, leading to the elaboration of this report. Digestive schwannomas or neurilemomas present a long and concealed clinical history, with anaemia arising from digestive haemorrhage when the tumour ulcerates and necroses leading to the diagnosis. Generally benign, they originate in the Schwann cell. Treatment is intestinal resection

Vascular ectasias of the right colon

K. Daskalakis, C. Kounoudes, D. Papoutsas, S Kapiris, P. Vernikos and G Diamantopoulos *3rd Surgical Department, 'Evangelismos' Hospital, Ipsilantou str Athens, Greece*

The aim of this study is to indicate the diagnostic and operative problems in managing patients suffering severe haemorrhage due to angiodysplasia (more accurately termed as vascular ectasia) of the right colon.

During the last decade six patients aged 62 to 82 years old required urgent laparotomy for lower gastrointestinal bleeding Preoperative emergency colonoscopy, as the first choice diagnostic procedure, was performed in all patients By way of colonoscopy it was feasible to distinguish whether the bleeding originated from the left or right colon. In one patient, it was impossible to distinguish the source of bleeding because of the coexistence of angiodysplasia in both right and transverase colon. The preoperative diagnosis which was performed by inferior mesenteric arteriography was accurate for vascular ectasias in three patients

Five of our patients had had right hemicolectomy, although the sixth one had a near total colectomy (the patient with the two synchronous angiodysplasias). No recurrence of the haemorrhage occurred during the immediate postoperative period The final diagnosis was made by the histopathological studies of the specimens

Vascular ectasias of caecum and ascending colon are important vascular lesions responsible for rare but severe lower gastrointestinal haemorrhage in elderly patients The main problem in treating such patients is to obtain accurate preoperative diagnosis, in order to proceed to the proper surgical technique. In cases with no certain arteriographic nor colonoscopic diagnosis, the choice of right hemicolectomy usually solves the therapeutic problem

Immunological state and erythropoietin (EPO) response in colorectal cancer

B. De Andres, J. Glez.-de-Zárate, R.A. De Andres, J. Rabadan, R. Bustamante and J. Bustamante *Departamento de Cirugia, Facultad de Medicina, Universidad de Valladolid, c/ Ramon y Cajal nº 7, Valladolid 47005, Spain*

Aim: Apparently, cytokines are involved in all of the major aspects of the pathogenesis of anaemia of chronic disease, namely inhibition of the proliferation of erythrocytic progenitors, impaired availability of iron, and lowers blood of EPO (W.E. Jelkmann, Annals New York Acad Sci 1994). For this motive we want to investigate immunological parameters and EPO levels in colorectal cancer patients.

Materials and methods: Following institutional ethics committee approval from University Hospital of Valladolid and informed consent of patients, TCD8, TCD4 and B lymhocytes, NK cells, immunoglobulins (Ig) G, M and A, the IL-2 receptor (RIL-2), haemoglobin (Hb), haematocrit (Ht) and EPO levels were measured in blood. We have compared these parameters in a group (Group 1) colorectal-cancer patients (n=20) vs a group of healthy people (n=20). The colorectal-cancer diagnosis was performed by colonoscopy with biopsy. All blood-specimen were taken before surgery. Statistical analysis of data was performed using ANOVA of repeat measurements and the Scheffé-test and the Pearson-correlation test, with significance documented at the P<0·05 level.

Results: Groups were comparable in terms of anthropometric characteristics. Results are shown in the following tables:

	Group 1	Group 2	Significance
TCD8 cells (%)	32·8±11	36·6±11	NS
TCD4 cells (%)	39·8±10	40·9±10·2	NS
B cells/ml	7·6±4·8	8·1±3·4	NS
NK cells (%)	22·1±12·7	19·1±10	NS
Ig G (UI/ml)	124·7±33	146·1±31·6	NS
Ig M (UI/ml)	171±70·7	176±69·4	NS
Ig A (UI/ml)	199·5±89·6	199·5±89·6	NS
RIL-2 (pM)	86·6±32·2	57·6±28	P<0·01

	Group 1	Group 2	Significance
Hg (gr/dl)	12·2±2·6	15·5±1·2	P<0·01
Ht (%)	38·8±6·7	46·3±3·4	P<0·01
EPO (mUI/ml)	20±5	8·6±3·1	P<0·01

We have found a significant correlation (r=–0·59, P<0·01) between the EPO-levels and hemoglobin in group 1, but none in group 2.

Conclusions: We conclude that EPO levels are inappropriately high in colorectal patients, in the early stage of diagnosis and this increase was correlated with haemoglobin levels. What can indicate an incipient anaemia or one must to consider it as a global event of the colorectal cancer.

Fluorouracil and high-dose leucovorin with radiotherapy as adjuvant therapy for rectal cancer. Results of a phase II study

F. de Lara, J. Giralt, D. Rubio, X. Maldonado, B. Sainz, J.L. Sanchez, E. Espin, J.M. Fort and M. Armengol *Dept. of General Surgery, Hospital General Vall d'Hebron, Paseo Vall d'Hebron 119-129, 08035 Barcelona, Spain*

Aim: The purpose of this phase II study was to evaluate the efficacy and toxicity of fluorouracil and high-dose leucovorin (5-FU/LV) with pelvic irradiation as adjuvant therapy for patients with macroscopical resected rectal or rectosigmoid cancer.

Material and methods: Following surgery for stages II–III primary (52) or recurrent rectal cancer (4), 56 patients received eight cycles of 5-FU/LV and pelvic irradiation. 5-FU doses were 200 mg/m^2 for cycles 2–3 and 300 mg/m^2 for cycles 1 and 4–8. LV doses remained fixed at 200 mg/m^2. Pelvic radiation was started in third week, between the first and second cycle. The total dose was 50·4 Gy.

Results: No severe complications had been recorded. The incidence of grade 3 diarrhoea was 19 per cent. Three patients presented leukopenia grade 3 (5 per cent). In 44 patients (78 per cent) the planned treatment could be administered. The median follow-up was 40 months (range 22–66). Seven patients had local relapse (13 per cent) and six developed distant metastasis (10 per cent). The three years disease-free survival was 72 per cent and the overall survival was 76 per cent.

Conclusions: These preliminary results show that combined postoperative 5-FU/LV and pelvic radiotherapy are well tolerated and present a reasonable local and survival rates. This adjuvant treatment should be evaluated in randomized trials.

Histopathological prognostic score in colorectal adenocarcinomas

M. Diez, M. Pollán, T. Ratia, J.M. Enríquez, A. Santana, E. Tobaruela, J.M. Mugüerza, F. Arrieta, A. Rodríguez, A. Ruiz and J. Granell *Cirugía General, Hospital Principe de Asturias, 28805 Madrid, Spain*

Aim: To evaluate the predictive value of p53 protein expression in gastric adenocarcinomas.

Material and methods: Eighty-nine patients operated on for gastric adenocarcinoma were included, all of them underwent curative gastrectomy (stages I, II, III of the Japanese Staging System). Immunohistochemical p53 protein expression was assessed in formalin-fixed paraffin-embedded tissue samples from the primary tumours (CM1 antibody). Relationship between p53 expression and histological type (Lauren classfication), depth of tumour infiltration in gastric wall, presence of lymph node metastasis and proliferative activity (PCNA labelling index). The relative importance of each factor on the risk of death was assessed by Cox's regression analysis.

Results: Thirty-three (37 per cent) tumours showed positive nuclear immunostaining and overexpressed p53 protein. Diffuse carcinomas were significantly more frequently p53-positive than intestinal carcinomas (44·6 per cent vs 24·2 per cent) (P=0·02). Tumours with high PCNA labelling index (>50 per cent tumour cells showing immunoreactivity) exhibit more frequently p53 positivity than tumours with low-moderate PCNA index (P=0·08). No relationship was detected between p53 immunostaining and staging, tumour site, depth of tumoral invasion in gastric wall and lymph node metastases. Thirteen (39·4 per cent) patients with p53-positive tumours and 11 (19·5 per cent) p53-negative tumours (P=0·02) died due to the gastric cancer. Cumulative probability of survival at 36 months after surgery was lower in p53-positive tumours (50 per cent vs 72 per cent) (P=0·01). Survival in stages II and III was lower for patients with p53-positive tumours (40 per cent vs 62 per cent) (P=0·03). P53 protein showed significantly independent predictive value in the multivariate analysis variables. The risk of death due to gastric cancer was 2·22 times higher (95 per cent CI: 1·1–4·47) in patients with tumours that showed overexpression of p53 protein.

Conclusion: Overexpression of p53 protein is a negative predictive factor, associated with lower survival, in patients operated on for gastric cancer. This test may be an aid to standard staging classifications for the identification of subpopulations with different prognosis.

Complications of ileal and colonic loop reconstruction during and following radical cystectomy

A. Eroğlu, A. Bilgin, B. Bozkurt, M. Karabeyoğlu, M. Kiliç, E. Ulusoy and M. Çetinkaya *Ankara Numune Hospital 2nd Urology and 2nd General Surgery Departments, Ankara, Turkey*

Complications during and following radical cystectomy and intestinal (ileal or colonic) loop or pouch operation performed in a total of 30 patients with Transitional Cell Ca during 1995–1997 by 2nd Urology and

2nd General Surgery Departments have been retrospectively evaluated in this study

Of these 30 patients undergone ileal or colonic loop/pouch, the mean age was found to be 57 3 years ranged between 30 and 72 years. The percentages of males and females were 89 4 and 11 6 per cent, respectively

In 23 patients, a free ileum segment that was 15 cm long with due protection of vascular band has been prepared and intestinal continuity was provided with end to end ileo-ileostomy In six patients, beginning from the proximal of the rectosigmoid junction a free sigmoid segment with 15 cm length has been prepared and continuity was provided with end to end colo-sigmoidostomy In one patient special Indiana Pouch that contains terminal ileum and coaceum has been prepared

In two patients to whom ileal loop has been prepared, an obvious vascular deficiency was observed at the line of anastomosis during operation Therefore, resection and reanostomosis were made. In another patient to whom colonic loop has been prepared an iatrogenic rectum injury that occurred at the time of prosthatectomy was corrected and a proximal protective loop colostomy was performed In a total of three patients a postoperative evisceration was developed and a second operation was needed for the correction. In 10 (33 0 per cent) out of 30 patients, there were some of the signs of intestinal obstruction during early postoperative period. This situation persisted for 3–6 days and they were only medically treated (correction of fluid and electrolyte balance, nazogastric decompession, early mobilization) Interestingly, none of them required a second look surgery.

Emergency colonic resection with anastomosis for diverticular disease and carcinoma complicated by peritonitis

U. Ginanneschi, P. Fabiani, M. Rizzi, G Fanti, L. Tenze,
F. Maghetti and E. Tendella *Istituto di Chirurgia Generale,
Università di Trieste, Italy*

Advances in surgical techniques and intensive care medicine have recently renewed the interest on the one stage treatment of diverticular disease and colonic carcinoma complicated by peritonitis The aim of this study is the evaluation of results of colonic resection with immediate anastomosis after these surgical emergencies

At our institution, one surgical team well trained in colorectal surgery performed a colonic resection with primary anastomosis in 19 patients (mean age 65 years, 30–90 years) with peritonitis. Seventeen patients (89 5 per cent) had ASA stage superior than II. The peritonitis was due to diverticular disease in 11 cases (58 per cent) and to colonic carcinoma in 8 (42 per cent) Five carcinomas were situated in the right colon and three in the left colon. According to the Hinchey's classification, the peritonitis was stage I in 13 patients (68 5 per cent), stage III in 2 patients (10·5 per cent) and stage IV in 4 patients (21 per cent)

All anastomoses (16 single layer extramucosal and 3 two layers handsewn) were performed on patients judged haemodynamically stable by the anesthetist. In one patient we performed Dudley's wash-out, and in 7 (37 per cent) we associated an other operation to the colonic resection (3 appendicectomy, 3 cholecystectomy, 1 right ovariectomy) The mean operating time was 3 h 20 min (2 h 30 min–5 h).

Eleven patients (58 per cent) developed postoperative complications not requiring a new operation, including 3 clinical anastomotic leakages (15 8 per cent). In two cases the fistulas closed spontaneously on short course of TPN Three patients (aged 78, 88 and 90 years) treated by left colon resection died for persistent sepsis (15·8 per cent), all of them were classified in the ASA IV group Two presented preoperatively a severe cardiovascular disease associated with a severe renal failure, one of these developed a minor anastomotic leakage.

Our data suggest that resection with primary anastomosis is a valid option for experienced surgeons in the treatment of diverticular disease and colonic carcinoma complicated by localized or diffuse peritonitis, either purulent or fecal In fact the mortality rate is mainly related to the dramatic effect of sepsis on preexisting severe organic disease

A more accurate selection among the patients in the group ASA IV requiring left colon resection, focusing on the negative effect of association between severe cardiovascular and renal failure, could probably reduce the rate of anastomotic leakage, also if it does seem not to affect the necessity of reoperations for persistent or recurrent peritonitis

The value of the faecal occult blood test in the diagnostic assessment of proctological patients?

J.H.P.M Jongen, M. Reh and J.-U. Bock *Proctological Office
and Department of Proctology, Park-Klinik, Goethestrasse 11,
24116 Kiel, Germany*

Because a complete diagnostic assessment of the colon in proctological patients is not feasible or possible, we retrospectively tried to find out, if the test on faecal occult blood (FOBT) has any benefit to diagnose a colorectal malignancy In our office endoscopy is limited to rectosigmoidoscopy or partial colonoscopy If the history, the findings at proctological examination and limited endoscopy do not give any clue for more proximal colonic disease, a FOBT was performed. This test was also repeated after any proctological treatment From 1991 till 1994 3015 FOBT's were evaluated. Two hundred and forty-four tests of 225 patients (105 males, 120 females, average age 55 years) were positive In 130 patients (58 per cent) an ileocolonoscopy or barium enema were performed one caecal carcinoma was found. In 19 patients we advised further colonic examination, but it was not performed. In this group a woman with anaemia died, who strictly declined the colonoscopy In the other 89 patients, in which diagnostic assessment was already performed or the FOBT was positive because of diet, medicines or prior haemorrhoidal therapy, two patients died (gastric cancer and myocardial arrest) This group of patients with positive FOBT was compared with a group of patients, in which a carcinoma in the anorectum or colon was diagnosed (60 patients, 19 males, 41 females)

The results of this retrospective study show, that the diagnostic use of the FOBT has no benefit in the diagnostic assessment of proctological patients to exclude a colorectal malignancy.

Application of stapling in colorectal surgery

D. Kaczmarczyk and W. Stryga *Warsaw District Traumatology
Hospital, Department of General Surgery, Barska str. 16/20,
02-315 Warsaw, Poland*

Aim: Most of digestive tract surgical procedures results with a need for performing anastomosis. This study aims to summarize the results of introducing a variety of stapler types and stapling techniques in intestinal anastomosis, during large bowel and rectum operations that finished with restoration of continuity of alimentary tract.

Material and methods: In the period October 1995–December 1997, 46 surgical procedures of large bowel and rectum, that included intestinal anastomosis, were performed A group of patients consisted of 21 male and 25 female, average age 68·3 Out of above mentioned procedures 30 cases were scheduled operations (65·2 per cent), 16 were emergency operations (34 8 per cent). Main surgical indications for intestinal resections were divided in two groups: new-growth tumours – 44 procedures (95·7 per cent of total) and others – 2 procedures (4·3 per cent of total). The following staplers were used for the reconstruction of the alimentary tract: circular CEEA, linear cutter GIA and linear TA.

Results: Out of 46 intestinal anastomosis recorded, in 23 procedures CEEA staplers were used, and in 23 procedures GIA staplers were used In all cases TA staplers used for closing colotomy. Seventeen of described above operations were anterior resection. The time of surgical procedure was shorten significantly and the degree of tissues trauma was decreased The application of staplers improved the conditions of healing, due to smaller interruption of blood supply in the area of anastomosis, resulting from proper staples placement and a limited tissue squeeze. In all described procedures a total number of one case of functional stricutre after CEEA stapler usage (i e 2 2 per cent of total) was recorded

Conclusions:

1 The application of stapling enables to perform low rectal anastomosis and avoids mutilating colostomy, even in emergency operations, ensuring at the same time the oncological radicality of the surgical procedure

2. Stapling technique allows to shorten the duration of colorectal surgical procedure significantly, improves aseptic and homeostasis due to limitation of infection with intestinal contents, comparing to cases when traditional suturing technique was used

3. The use of staplers has proven to decrease the number of postoperative

complications, connected with insufficient tightness, bleeding and stricture in the anastomosis area.

L-glutamine but not short chain fatty acids attenuates the inflammation and oxidant injury in experimental colitis

E. Kaya[1], E. Gür Sürmen[2], R. Tokyay[1], H. Özgüç[1] and A. Bayer[3]
Uludağ Univ. Med. Sch. Departments of [1]Surgery, [2]Biochemistry and [3]Pathology, 16059 Bursa, Turkey

Short chain fatty acids (SCFA) and L-glutamine are metabolic fuels for colonocytes. The aim of this study was to investigate the role of L-glutamine and SCFA enemas on mucosal damage and inflammation in experimental colitis.

Methods: Colitis was induced with trinitrobenzenesulphonic acid in ethanol (TNBS-E) in rats. Saline (n=14), prednisolone (n=13), mesalazin (5-ASA) (n=14), L-glutamine (n=14) and SCFA (n=13) enemas were applied twice daily to the rats for 7 days after induction of colitis. Sham group (n=9) received only saline enemas. Rats were killed on the seventh day and their colonic macroscopic inflammatory scores (MIS) were determined. The activity of mucosal gamma glutamyl transpeptidase (GGT) and plasma, liver, colonic mucosal molondialdehyde (MDA) levels were measured. Same measurements but no enemas were done in the control group (n=7).

Results: There were significant differences in MIS between sham and colitis (P<0·001) groups. The MIS of the colitis group was higher than SCFA and glutamine groups (P<0·05). While the mucosal GGT activity was diminished in prednisolone, 5-ASA and SCFA groups when compared to the control, in colitis, sham and L-glutamine groups this enzyme activity did not change. The colonic mucosal, liver and plasma MDA levels were significantly less in the prednisolone and glutamine groups than the colitis group.

Conclusion: L-glutamine enemas decreased the severity of colitis both morphologically and biochemically. L-glutamine had also an antioxidant effect in colonic mucosa, liver and plasma.

The risk of lymph node metastases in pT1 rectal cancer

F. Martin, P.L. Catalano, G. La Guardia, A. Frena and R. Polato
Second Surgical Department, Regional Hospital Bolzano, Böhlerstraße 5, 39100 Bolzano, Italy

The purpose of our study was to identify pathologic parameters of pT1 rectal cancers related to the risk of lymph node metastases (LNM). The assessment of this risk is of crucial importance to select patients eligible for local excision of rectal cancer.

Materials and methods: A total of 301 patients underwent resection for rectal cancer. In 25 cases (8·3 per cent) the tumour extended into the submucosa without invasion of the muscolaris propria (pT1). The slides from these 25 tumours were re-examined.

Statistical comparison between patients with and without LNM was performed considering the single follow variables:

- size of the tumour: diameter <30 mm vs diameter >30 mm;
- cellular differentiation: G1–2 vs G3–4;
- lymphatic vessels invasion: presence vs absence;
- high-risk histology vs low-risk histology.

Lesions with low degree of cellular differentiation (G3–4) and/or with signs of lymphatic vessels invasion were classified as having a 'high-risk histology'.

Results: LNM were found in four out of 25 tumours (16 per cent). Only one of the four tumours presenting LNM were smaller than 30 mm. In the group of the 23 well or moderately differentiated tumours (G1–2) only two showed LNM.

The size of the tumour and 'high-risk' histology were found to be statistically significative to determine the risk of LNM.

Conclusions: Our data suggest that tumours of the low and middle third of the rectum smaller than 30 mm well-differentiated and without lymphatic vessels invasion have a low risk for LNM and should be considered for local excision.

Synchronous hepatocellular carcinoma and adenocarcinoma of the rectum. Case report and review of the literature

Z. Máthé, Gy. Végsõ, D. Görög, M. Puhl and F. Perner
Semmelweis Medical University Dept. of Transplantation and Surgery, Baross u. 23, H-1082 Budapest, Hungary

Introduction: Multiple tumours are particularly frequent in some types of cancer, such as colorectal, breast, head and neck carcinomas. A review of the literature indicates that the incidence of synchronous tumours of the colon and rectum ranges from 2–12·4 per cent. The incidence of synchronous extra-colonic malignancies is less well defined, but it appears to be 0·7–6·7 per cent. The reasons whereby a subgroup of patients develop more than one malignancy remain unclear and in this respect multiple tumours represent a biological challenge.

Aim: The aim of the study is to summarize the presentation, clinical investigations and treatment of a patient with synchronous hepatocellular carcinoma and adenocarcinoma of the rectum and to remind the possibility of simultaneous malignancies.

Case report: The patient was a 53-year-old man whose medical history revealed diabetes mellitus, transient ischaemic attack and alcoholic liver disease associated with mild liver cirrhosis (Child A). A routine clinical check up (physical examination, abdominal ultrasonography and later CT scan) revealed a 6 cm tumour in the VI–VII segment of the liver. The needle biopsy showed hepatocellular carcinoma. During the investigations rectal bleeding occurred, rectoscopy and colonoscopy with biopsy demonstrated an intraluminal rectal adenocarcinoma. As the first step abdomino-perineal resection was performed, histology showed $pT_2N_0M_0$ rectal adenocarcinoma. Three months later after a control check up the encapsulated liver tumour was resected. Metastases were not found, histology showed hepatocellular carcinoma. There were no intraoperative or postoperative complications.

Conclusions: The literature has highlighted the incidence of synchronous colonic neoplasms, but the risk of a second carcinoma developing at extracolonic site also must be considered in patients with colorectal tumours. Although simultaneous rectal carcinoma and hepatocellular carcinoma is extremely rare in the literature. The authors emphasize the need for detailed preoperative clinical investigations to find not only the metastases but both synchronous colonic and extracolonic malignancies.

Immunobiological approach to colon cancer staging: retrospective evaluation and prospective trials after 15 years' experience

G. Midiri, M.R. Giovagnoli, A. Tesoriere, E. Giarnieri, A. Lombardi and A. Bertolotti *IV Clinica Chirurgica, Università di Roman 'La Sapienza', Policlinico Umberto I, 00161 Roma, Italy*

In spite of recent progress achieved in early diagnosis through endoscopy, and in surgical treatment with the help of new technology and in new adjuvant radio-chemotherapy protocols the colon cancer death-rate has not yet been reduced. We consider as a possible explanation of this failure the inadequacy of the present colon cancer staging criteria, that do not allow to characterize the effective biological activity of the disease and appear likewise not to coincide with the neoplasm's natural history. When we started our experiences on this topic the basic question was the folowing: is it possible to classify and to stage colon cancer not only on the grounds of its diffusion, histological type and grading, but on the grounds of its biological expression as well?

At the outset we tried to design experimental models integrating biological markers (serum and tissue CEA levels) and standard staging parameters (TNM-UICC, Duke's classification, grading) in 193 patients operated on colon cancer. In spite of the employment of several serum new biomarkers for the staging and the monitoring of colon cancer patients, serum preoperative and postoperative CEA evaluation is to date considered the most reliable test for clinical application in colon cancer. K-Ras serum pre and postoperative test is up to day under evaluation.

Retrospective and prospective evaluations about cellular 'in situ' immunological response did not show correlation with colon cancer staging.

Intranuclear DNA imaging may be to day considered as a marker of the biological behaviours of colon cancer Our results achieved on 20 patients seem to confirm the data of literature: high proliferative cellular activity and aneuploidy appear correlated only with the extent of the primary tumour ($P=0.022$) and with a severe prognosis, but by multiple full thickness sampling performed by through-cut biopsy by Silvermann-like needle we noticed that the most atypical clones were present in samples taken from the infiltrating part of the tumour, near the serosa

Reconstruction of colonic continuity following the Hartmann operation: risky surgery?

E. Montalvá, A. Vázquez, E. Artigues and R. Trullenque
Service of General and Digestive Surgery, Valencia University General Hospital, Valencia, Spain

Aim: The Hartmann operation remains indicated in both emergency and programmed surgery. In many cases the patient may be subjected to a second operation to restore colon continuity In this sense, a correct evaluation of the risk/benefit ratio is essential to decide the convenience of this second reconstruction operation

Material and methods: A review is made of the case histories of patients subjected to terminal colostomy closure after the Hartmann operation in the period 1991–1996, with an evaluation of the morbidity-mortality statistics involved

Results: A total of 23 patients (16 males and 7 females) were studied. Mean age was 54 years (range 29–73). These patients represented 25 per cent of all Hartmann operations performed in this same period. In all cases initial surgery was carried out on an emergency basis (17 due to benign pathology and 6 for tumours). The mean time elapsed between the two operations was 10 months (range 2–21) The surgical technique adopted for reconstruction was not uniform. There were posterior complications in five patients (21·7 per cent). two wound infections, one pleural effusion, one Douglas haematoma, one case of moderate faecal incontinence, one eventration, and one case of anastomatic dehiscence. Mortality was zero

Conclusion: In emergency surgery of the left colon the techniques of choice are resection with primary anastomosis and the Hartmann operation. In our series major reconstruction morbidity following Hartmann's operation was 8·7 per cent, with zero mortality. Thus, surgery for reconstructing colon, continuity does not pose excessive problems in those patients subjected to the Hartmann operation.

Local recurrence after rectal resection for cancer. Retrospective study in 154 cases (1970–1991)

S. Neagu, S. Rohr, N. de Manzzini, Ch. Thiery and Ch. Meyer
Department of Digestive Surgery, University Hospital Hautepierre, Strasbourg, France

From 1970 to 1991 we performed 154 rectal resections 88 anterior resections Knight, 27 anterior resections Dixon, 33 Hartmann operations, 6 other resections (Kraske – 2, Babcock – 2, Duhamel – 1, van Hackenegg – 1). The surveying program included 114 cases The local recurrence (L R) appeared in 32 cases (28 1 per cent) From 1988 we introduced the preoperative radiotherapy in all cases and that was an important element in reducing the risk of L R the incidence of L.R. before 1988 was 29 3 per cent (28 from 77 cases); for the cases with preoperative radiotherapy the incidence of L.R. was 6 2 per cent (two from 32 cases).

The L.R. appeared in 78·1 per cent cases in the first 2 years and only in 12·5 per cent cases in the third year postoperatively. The incidence of L.R was related with the tumour stage· 0 per cent for stages A and B1; 16 7 per cent for stage B2 and 50 per cent for stage C

The position of the recurrence was· anastomotic in 9 cases (28·1 per cent), pelvic in 18 cases (56 2 per cent) and we have no position data in 5 cases (15 6 per cent) The resection of L.R was possible in 11 from 32 cases (34 4 per cent) The survival at 5 years for the cases with L R was 18·7 per cent. There was no case alive at 6 years

The influence of age on prognosis and management of patients with colorectal carcinoma

P. Melih, L Turgut, A. Ismail and C. Hayrettin *Dept. of Surgery, Cerrahpasa Medical Faculty of Istanbul University, Istanbul, Turkey*

Aim: To examine the factors affecting prognosis and management of patients younger than and older than 65 years of age with carcinoma of colon and rectum.

Materials and methods: 822 consecutive patients with colorectal cancer who had operative treatment between 1984 and 1994 were studied retrospectively. Patients were divided into two groups and compared. Group 1 included 565 patient aged less than 65 years, Group 2 comprised 257 patients aged 65 or more.

Results: There was no significant difference between the two groups with regard to the mode of presentation, the location and type of pathology, the histological grade, the incidence of curative and palliative operations, and the postoperative morbidity and mortality The obstruction and perforation was more common in in the elderly ($P<0{\cdot}0001$) Clinical relevant postoperative complications were observed in 20 per cent of patients in Group 1 and 25 per cent of patients in Group 2 ($P>0{\cdot}05$). Four per cent and 7 per cent of patients in Group 1 and 2 had an anastomotic leakage ($P>0{\cdot}05$) The postoperative mortality rate was 3·4 per cent for younger group and 6·6 per cent for older group ($P>0{\cdot}05$) Of these patients. 3·1 per cent and 20 7 per cent in Group 1 and 6 per cent and 25 per cent in Group 2 underwent elective and emergency surgery respectively ($P>0{\cdot}05$) The mortality rate was higher in those who underwent emergency surgery but was not significantly related to the age. The actuarial 5-year survival rates for older and younger patients were 33 and 45 per cent respectively ($P<0{\cdot}05$)

Conclusions: Age alone has no characteristic effect in the treatment of colorectal carcinoma.

Surgery for local recurrence of rectal carcinoma

M.J. Palacios, A. Güemes, J.M. Ramírez, F. Burdío, R. Sousa, M. Suárez and R. Lozano *Servicio de Cirugía 'A', Hospital Clínico Universitario, Zaragoza, San Juan Bosco s/n, 50009 Zaragoza, Spain*

Introduction: Local recurrence of rectal cancer after surgical resection with curative intent occurs early, about 70–80 per cent within the first 2 years of follow-up after previous curative therapy The symptoms at presentation are different, depending on surgical treatment of primary tumour. A rigorous follow-up after resection of primary colorectal cancer including endorectal ultrasonography lead to detect early recurrence.

Aim: The aim of this study is to evaluate surgical treatment in patients with local recurrence of rectal carcinoma

Patients and methods: Between January 1992 to December 1997 10 patients underwent intention for local recurrence of rectal carcinoma after curative resection. We have analysed, previous surgery with curative intent, original stage, free interval time to recurrence, symptoms of recurrence site of recurrence, treatment, survival-time.

Results:

	Surgery	Dukes	Time to recurrence	Symptoms	Site of recurrence	Treatment	S
Case 1	AR	A	12 m	Pain	Extralumen	APR	A
Case 2	APR	B	22 m	Pain	Extralumen	Local resection	A
Case 3	AR	B	1ª–12 m	Rectal blood	Anastomosis	AR	D
			2ª–36 m	Pain	Extralumen	APR	
Case 4	APR	C	36 m	Pain	Extralumen	Local resection	D
Case 5	AR	C	14 m	Rectal blood	Anastomosis	APR	A
Case 6	AR	C	1ª–12 m	Rectal blood	Anastomosis	APR	A
			2ª–36 m	Pain	Extralumen	Local resection	
Case 7	AR	C	21 m	Rectal blood	Anastomosis	Hartman	D
Case 8	AR	C	48 m	Rectal blood	Extralumen	Palliation	D
Case 9	AR	C	6 m	Pain	Extralumen	Colostomy	D
Case 10	AR	B	12 m	Pain	Extralumen	APR palliative	A

AR. anterior resection, APR abdominoperineal resection, S. survival, D died, A· alive

Median time to recurrence was 22 months. The symptoms were anal pain and rectal blood. patients treated with AR the recurrence was at the anastosis and required an APR was performed initially, the site of recurrence was extralumen. Fifty per cent of the patients were treated with radiotherapy too.
Conclusions: In the treatment of locally recurrence colorectal cancer the approach is multidisciplinary and based on previous radiation therapy and surgical resection. The influence of early detection of local recurrence on resectability and prognosis is stated so its important to detect it in asymptomatic period.

Evaluation of neuromodulation in patients with rectal dyschezia and voiding dysfunction

P. Pattyn, K. Everaert*, F. Berrevoet, A. Cardon, D. De Looze** and B. de Hemptinne *Dept. of Surgery, *Dept. of Urology, **Dept. of Gastroenterology, University Hospital, De Pintelaan 185, 9000 Gent, Belgium*

Recent results from the Marks clinic show the use of neuromodulation in treatment of both rectal dyschezia and voiding dysfunction. The aim of this study was to determine which patients with rectal dyschezia and voiding dysfunction might be suitable for treatment with neuromodulation.
Patients and methods: Twenty-seven patients were included in the study and selected for implantation of a neuroprosthesis using a urodynamic evaluation before and during subchronic stimulation. A Medtronic screener and a Flexon wire were used for neuromodulation. Four men and 20 women were included with a mean age of 33±15 years. In this group eight patients were suffering from rectal dyschezia and one patient had severe incontinence.
Results: After implantation of the neuromodulation only two patients still had complaints of dyschezia and incontinence was no longer present in these patients. Of 10 patients with spastic pelvic floor syndrome, nine responded well to the treatment. Those not responding to neuromodulation had mainly acontractile detrusors.
Conclusion: The ideal candidates for neuromodulation are those patients with a spastic pelvic floor syndrome or with an anatomical dysfunction that is not easily treated surgically.

Prognostic value of carcinoembryonic antigene (CEA) in colorectal cancers

E. Reis, M. Güvel, G. Daglar, T. Coskun, E. Kesici and N.A. Kama *Ankara Numune Hospital, 4th Department of Surgery, Ankara, Turkey*

Introduction: It has been shown the CEA is an independent prognostic factor in colorectal cancers. In this study, the relation between preoperative CEA level and morphological and pathological features of tumour, stage, relapse and mortality were investigated.
Patients and methods: Between 1990–1997 67 patients were operated on due to colorectal cancer. There were 36 male patients and 31 female patients. The ages of patients ranged between 23 and 83 (median 56 years). The tumour was present in the right colon in 18 patients, in the left colon in 20 patients, in the rectum in 28 patients and in both right and left colon in one patient. There were 2 (3 per cent), 26 (38·8 per cent), 28 (41·8 per cent), 11 (16·4 per cent) patients in Dukes A, B, C, D stages respectively. The mean follow-up time was 35 months. The patients were divided in the two groups: (a) normal CEA level (<5 ng/ml), (b) high CEA level (>5 ng/ml). The CEA level was normal in 42 patients (62·7 per cent) and high in 25 patients (37·3 per cent). These two groups were compared concerning 20 different parameters including morphological and pathological features of tumour, relapse and mortality. Survival analysis was evaluated with the use of Kaplan Meier long rank method and other parameters were evaluated with the use of Chi-square test.
Results: When the relation between CEA levels and 20 parameters were evaluated, a relationship was determined among the tumour size, liver metastasis, tumour fixation, haemoglobin level, pathological TNM stage, relapse and mortality ($P<0{\cdot}05$). In univariate analysis, it has found that the patients with normal CEA levels survival longer than the patients with high CEA levels (69 months vs 25 months) ($P=0{\cdot}0001$).
Conclusion: This result of this study has shown that patient with high CEA level had large, fixed tumour with high incidence of liver metastasis and poor survival. Preoperative high CEA levels may be an indicator of advanced intraabdominal disease and poor outcome.

Ultra-low coloanal anastomosis for rectal carcinoma of the anorectal junction

E. Rullier, C. Laurent, F. Zerbib, J.L. Garrelon, J. Saric and M. Parneix *Saint-André Hospital, 33075 Bordeaux, France*

Aim: Traditionally, radical resection of low rectal carcinoma of the anorectal junction (tumour located at 1 cm or less from the anal ring) is abdominoperineal resection because of the necessity of both to achieve a 2 cm distal margin and to preserve anal sphincter integrity. The aim of this study was to investigate functional and oncological outcome of ultra-conservative resection for rectal carcinoma.
Methods: Among 261 patients treated for rectal carcinoma, between 1990 to 1996, 16 consecutive patients (10 males, 6 females; age 64) had conservative resection for a lesion of the anorectal junction. All the tumours involved the bowel wall at digital examination and at endorectal ultrasonography and were contraindicated for local excision. The mean distances between the tumour and the anal verge, and between the tumour and the anal ring, were respectively 3·62 cm and 0·84 cm. Rectal resection with resection of the internal sphincter was carried out, allowing a distal margin of 2 cm in all cases. An ultra-low coloanal anastomosis was performed, in association with a colonic **J** pouch in half patients. Twelve patients (75 per cent) had preoperative radiotherapy. Dukes' modified stage of the tumour was: B1=8, B2=1, C1=1, C2=4, sterilized=1, D=1.
Results: There was no postoperative mortality. Two patients had permanent colostomy for pelvic haemorrhage and anovaginal fistula. After a mean follow-up of 42 months (range 9–89), two patients died from distal metastases and there was no local recurrence. Actuarial survival was 75 per cent at 5 years. Continence (Kirwan scale) was normal for half of patients and was altered (occasional minor leak) for the other patients. Functional results were similar after partial resection of internal sphincter than after subtotal resection, but they were better after pouch than after straight anastomosis.
Conclusion: Local recurrence rate and long-term survival were not affected by conservative resection for rectal carcinoma of the anorectal junction, which can be an alternative to abdominoperineal resection for selected patients. Furthermore, our results suggest that performing a colonic pouch is most important that preservation of internal sphincter to achieve good functional results after ultra-low coloanal anastomosis.

Hereditary nonpolyposis colorectal cancer and Turcot's syndrome

M. Salvador Fernández, J. Martín-Benito, J. Vazquez-Echarri, A. García-Alvarez, D. Lacasa, E. González, S. Piñero and J.L. Martínez-Veiga *Servicio Cirugía General y Digestiva, Hospital Insalud "Severo Ochoa', Avda Orellana s/n, Leganés 28911, Madrid, Spain*

Aim: The aim of the present study is to report the case of a family with the hereditary nonpolyposis colorectal cancer (HNPCC) syndrome in association with Turcot's syndrome.
Introduction: Turcot's syndrome denotes the syndrome of familial adenomatous polyposis (FAP) and a primary tumour of the central nervous system. Using molecular evidence Hamilton *et al.* defined two germ-line defects associated with Turcot's syndrome, one of which is usually found in FAP, and the other is usually found in HNPCC.
Material and methods: We studied families with HNPCC that included a patient with a primary brain tumour. The families were identified from the HNPCC Registry that we are performing in our hospital. HNPCC was defined according to the criteria of the International Collaborative Group.
Results: We found a family with a 16 year-old male member who developed a glioblastoma involving the right parietal area of the brain.
Discussion: Two major inherited syndromes with colorectal neoplasia can now be characterized, FAP and HNPCC. In FAP there is a germ-line alteration of the adenomatous polyposis coli (APC) gene. In HNPCC a

germ-line mutation occurs in one of a group of genes involved in DNA nucleotides mismatch repair, including *hMSH2*, *hMLH1*, *hPMS1*, *hPMS2* Molecular genetic work has found that about two-thirds of cases of Turcot's syndrome arise from mutations of APC gene, whereas one-third come from mutations of mismatch repair genes, the same genes mutated in HNPCC The central nervous system tumour are also distinctive depending on which gene is mutated, those with FAP syndrome exhibit medulloblastoma-type tumours, meanwhile HNPCC syndrome is associated with glioblastoma multiforme tumours, like our case.

Conclusions: Central nervous system tumours in HNPCC have not been well documented and require further investigation. Symptoms and signs suggesting central nervous system tumour in HNPCC families require prompt and careful investigation

Large bowel volvulus

S. Sekulic, R. Kosanovic, B. Lazic, P. Simic and D. Zlta
Medical Faculty, KBC, Surgical Clinic, Pristina, Yugoslavia

Intestinal destruction is a common pathology in the Kosovo an Metohija population. Although the incidence of large bowel volvulus is decreasing, cases continue to present.

From 1993 to 1997 there were 38 cases of large bowel volvulus, 23 cases were men and 18 were women. The mean age was 55 years Thirty-four patients had volvulus of the sigmoid colon and 4 had volvulus of the caecum Seven of the sigmoid and 2 of the caecal cases had gangrene.

Sixteen patients were treated with a Hartmann operation, sigmoid colectomy with primary anastomosis in 12 cases, right hemicolectomy in 2 cases and detorquation with fixation in 8 cases Postoperatively there were 6 wound infections, 2 wound dehiscence, 2 stoma complications, 1 myocardial infarction and 5 other cases of cardiorespiratory complications There were 5 deaths in this series

According to analysis of the series of our patients with large bowel volvulus, we noticed that the most important role in the appearance of volvulus is accustomed or congenital predisposition. In our series, volvulus of sigmoid colon according to older age is the result of accustomed predispositions, and the rotation is to the left

Surgical treatment of tumours of the right colon

M. Smiljkovic, R. Djordjevic, V. Kulic, M. Jovanovic,
M. Miladinovic, A Kitanovic, M. Gajic, D. Stankovic and
V. Milojevic *Health Centre Krusevac, Department of Surgery,
Krusevac, Yugoslavia*

In this article we give our experience in operative treatment of the tumours in the right colon in last 6 years. Retrospectively analysed data were gathered from history and operative records for 61 operated patients (20 per cent of all operated carcinomas of colon and rectum). The relations of sexes was nearly equal (31·30 male:female) Almost 41 per cent (25) of operated patients were in the group of the seventh decade, and 97 per cent (59) of them were older than 50. According to localization 50 81 per cent (31) belongs to coecum, 37·71 per cent (23) to ascending colon, and 11 48 per cent (7) to hepatal flexure as well as the transverse colon Resectability was 67 21 per cent (41). Right hemicolectomy with systemic lymphadenectomy was performed in all resectabe tumours Paliative operation in 32 79 per cent (20) were performed by ileotransversostomy As postoperative complications we had 2 (3·2 per cent) fistulas, 7 (11 4 per cent) supurations and 5 (8 per cent) deshicenties of operative wound, 2 (3·2 per cent) eviscerations and 2 (3·2 per cent) cardiopulmonary complications. Postoperative mortality rate was 1·64 per cent (1). The adenocarcinoma was verificated in 59 cases (96 72 per cent). Anastomosis after resection was created as termino-terminal in 20 cases (32 78 per cent), and termino lateral in 41 cases (67 22 per cent) one row continued or single modified suture by Gambe in 40 cases (65 57 per cent), and double file suture in 21 cases (34·43 per cent). By TNM classification, in 46 cases (75 4 per cent) after radical operation was found $T_2N_1M_0$. An appropriate diagnostic studies performed in early stages of illness may lead us to early and more radical surgery that can only give us a hope in longer life expectancy

Colonic obstruction: emergency resections with anastomosis

G. Stanojević, M. Stojiljković, D. Marić, D. Miljković and
D. Mihajlović *Surgical Clinic Clinical Center Niš, Braće
Taskovića 48 Niš, Yugoslavia*

Choice of surgical options in the treatment of colonic obstruction is still controversial Many authors suggest one stage procedure in colon obstruction because of elimination of the distended colon as a source of postoperative morbidity and mortality and reduction of the risk of malignant disease spreading. Between 1992 and 1996 in Surgical Clinic of Niš 270 patients were surgically treated because of the colon cancer (rectum excluded). In 81 patients (30 per cent) the disease manifested as an acute obstruction. Of 81 patients, 19 patients were younger than 65 years of age (23·45 per cent) and 62 (76 55 per cent) older than 65 years of age (range 38–86). Sex ratio was 54 per cent male and 46 per cent female. In 50 (62 per cent) patients, with 'closed loop', syndrome, we have done one stage resections with primary anastomosis In cases of the right colon obstruction we have done the right hemicolectomy 66 per cent (33 patients) and for the left colon obstructions we have done the subtotal colectomy 34 per cent (17 patients) We did not perform segmental colectomy and intraoperative colonic lavage 20 patients (40 per cent) presented with one or more associated medical at the time of operation In the subgroup treated with subtotal colectomy, complications occurred in 6 of 17 patients (35 per cent) and postoperative mortality was 11·7 per cent (two patients died, one as a result of anastomotic dehiscency and stercoral peritonitis the other as a result of pulmonary embolism) In the subgroup treated with right hemicolectomy morbidity was 27·2 per cent (nine patients) and mortality was 9 per cent (three patients died. one as the result of cardiopulmonary insufficiency, second as the result of cerebral ischaemic attack and third as the result of anastomotic leakage) Our opinion is that the low postoperative morbidity and mortality in the present series justify application of one stage resection as the safe method in the treatment of many obstructive cancers of colon ('closed loop') when performed by experienced surgeons in colorectal surgery

Synchronous colo-rectal carcinoma. Diagnostic and therapeutic implications

A. Stracqualursi, F Mosca, G Lipari, F. Latteri and S. Latteri
Department of Surgery, University of Catania

The reported prevalence of synchronous primary adenocarcinoma of the colon and rectum ranges from 2 to 9 per cent.

In a series of 723 patients with colo-rectal carcinoma treated consecutively from November 1973 to April 1997, seven patients (0·96 per cent) were identified to have a double carcinoma (synchronous cancers), located in separated colonic areas Patients with familiar polyposis or inflammatory bowel disease were not included in this study All patients were male and the average age was 55 4 years (range 42 to 80 years).

The cancers were located in different segments: two patients had the index carcinoma located in the caecum and the synchronous in the sigma, two others in the ascending colon and in the sigma respectively, one in the sigma and in the transverse colon, one in the rectum and in the caecum and the last in the transverse colon and in the ascending colon.

Preoperative diagnosis of synchronous lesions was achieved in only two cases. Endoscopy was performed in all patients, while air contrast barium enema studies were recorded for only two patients. In five patients the synchronous lesion was identified by palpation during laparotomy

Tumours were staged in accordance with TNM staging of colonic and rectal cancer. TNM staging of index cancer (the most malignant lesion) revealed four patients in stage II (Dukes' B classification), one patient in stage III (Dukes' C) and two patients in stage IV (Dukes' D).

In regard to extent of the resection in two patients the carcinomas were so remote that total colectomy was necessary. In other three cases we elected to employ a conservative policy, resecting each growth radically through a right hemicolectomy in conjunction with a sigmoid resection in two cases In two patients with a metastatic synchronous cancer cecostomy or ileostomy were performed

There were no hospital death and morbidity. We do believe that surgical strategy may change based on preoperative and perioperative total colonic evaluation. Second lesions must be identified because the location of synchronous tumours should infuence the extent of primary colonic resection. We agree with most authors on the need of full examination of the colon in all patients presenting with primary colorectal cancer and pancolonoscopy should be used as routine effective screening for synchronous cancers so that optimal initial treatment can be delivered. The choice of surgical proceeding is based on multiple factors, such as neoplasm's characteristics and location, the number of lesions and the grade of colonic dilation in the obstructing tumours: all patients require a more large resection and subtotal colectomy, when possible, is the gold standard treatment.

The Hartmann's operation for the treatment of colorectal diseases

M. Szczepkowski, W. Waśkiewicz, G. Gil., P. Skoneczny, M. Chojnowski and K. Górnicki *Second Surgical Clinic, Bielany Hospital, Ceglowska str. 80, 01-809 Warsaw, Poland*

Aim: The aim of the study is to present the authors experience with Hartmann's procedure.
Material and methods: Between January 1990 and October 1997 the Hartmann's operation was performed in 58 cases. Average age of patients was 67·3 (range 37–90 years). Fifty patients were operated in case of colorectal cancer and eight because of complicated diverticular disease and others. Clinico-pathological staging (Dukes' scale) for cancer tumours was: Dukes' A – 0 cases, Dukes' B – 12 cases (28 per cent), Dukes' C – 29 cases (58 per cent), Dukes' D – 9 cases (18 per cent). Majority of patients (49 cases – 84·5 per cent) were operated on emergency in case of intestinal obstruction or/and peritonitis.
Results: Postoperative complications were observed in 36·2 per cent of patients (21 cases) mostly due to surgical wound infection (14 patients – 24·1 per cent). Four of the patients (6·8 per cent) died in the postoperative period. All patients who died were operated in emergency because of complicated colorectal cancer and they had very serious additional diseases. Mean age of patients who died was 74 years. Mean hospital stay was 17 days.

After a mean period of 140 days (60–380 days), the continuity of the gastrointestinal tract was restored in 50 per cent (4 out of 8) patients who had survived the Hartmann's procedure performed in non neoplastic diseases, and in 16 per cent (8 out of 50 cases) only of patients who had undergone surgery due to carcinoma. In 58 per cent of patients (7 out of 12) intestine was anastomosed by circular stapler. In four patients (33 per cent) decolostomy was performed laparoscopically (laparoscopically assisted). In this kind of operation can be problems with intraabdominal adhesions, liberation stoma from stomal canal and identification of the rectal stump. Mean operating time laparoscopically assisted decolostomy was 155 min, mean hospitalization time – 6·5 days. There were no postoperative complications.
Conclusions:
1. Hartmann's operation allows patients to survive a fecal peritonitis and neoplasmatic obstruction and it can be performed when the intestinal anastomosis is too risky.
2. High complication rate is connected by relatively high percentage of advanced cases.
3. Laparoscopic assisted decolostomy after Hartmann's operation looks like a save procedure and in the future it can cause increase number of patients who had decolostomy which will improve the quality of life a lot.

Pyoderma gangrenosum at the parastomal site in patients with inflammatory bowel disease

R. Valanzano, E. Di Fonzo* and F. Tonelli *Dipartimento di Fisiopatologica Clinica, Unita' di Chirurgia and *Clinica Dermosifilopatica I, Universita' degli studi di Firenze, Italy*

Aim: Pyoderma gangrenosum (PG) is a rare skin disease, characterized by chronic, deep, necrotizing ulcers, usually localized at the lower extremities. In 30–40 per cent of cases, PG is associated with inflammatory bowel disease (IBD, either ulcerative colitis (UC) and Crohn's disease (CD), especially with active disease. The occurrence of PG at the parastomal site has been rarely reported.
Material and methods: Parastomal PG at the ileostomy site was observed in six female patients (5 UC and 1 CD patients; mean age 44·8 years, range 27–61 years). In three cases PG occurred from 4 to 8 weeks after total proctocolectomy, ileoanal anastomosis (IAA) and temporary diverting ileostomy for UC. Only one patient (patient 1) showed active disease (severe pouchitis, pelvic abscess and laboratory findings of inflammation). In two patients PG appeared four weeks after total colectomy and Hartmann's procedure for severe UC. In one of them proctoscopy revealed severe proctitis and laboratory findings of inflammation were present. The CD patient developed PG seven years after ileorectal resection with Hartmann's procedure for recurrent disease. No symptoms or signs of disease were present. A skin biopsy of the ulcer was obtained in three patients and was entirely compatible with PG diagnosis. Cultures of the skin lesions were positive for *E. coli* only in patient one. Oral methylprednisolone (16–40 mg/day) was administered in all patients associate to intralesional steroid injection.
Results: Complete healing of the skin lesions was obtained in two patients with inactive disease and partial healing in the CD patient. Replacement of the ileostomy was necessary in the other cases.
Conclusions: Although PG is usually described in associated with active disease it may run a course independent of intestinal disease activity and respond poor to intestinal resection. In our experience PG was associated with active disease in two out of six patients (33·3 per cent) and replacement of the ileostomy was necessary to resolve the PG. The other four patients did not show any sign of active disease. However medical therapy was unsuccessful also in two of them.

Abdominoperineal resection of the rectum for cancer: results with the Lazaro da Silva continent perineal colostomy

N. Velitchkov, G. Kirov, J. Losanoff, K. Kjossev and E. Anev
Departments of Surgery and Medicine, Military Medical Academy, P.O. Box 159, 1606 Sofia, Bulgaria

Aim: To assess the technique of continent perineal colostomy described by Lazaro da Silva as a new alternative to abdominal colostomy. To prove the effectivenss of this technique and its capability to produce neoanal continence in the long term. The technique is based on hindering of the colonic transit by physically uncoupling myoelectric activity and creating circular valves in the colon, thus, it was decided to assess its reproducibility by different surgeons.
Materials and methods: Between 1994 and 1997, 16 patients with low rectal cancer underwent the procedure. The technique consists of: 1) disruption of the myenteric plexus by performing three circular seromuscular incisions in the passing down the pelvic floor sigmoid colon; 2) construction of three circular valves at the sites of seromyotomies for mechanical hindering of the stool passage, and 3) achievement of regular defecations by means of self-performed enemas through the perineal colostomy.
Results: Of the patients, 56 per cent (n=9) were Dukes' A and 44 per cent (n=7) Dukes' B with their age in the range 46–69 years (median, 59·3). There were no deaths and no tumour recurrences have occurred so far. Thirty-eight per cent of the patients (n=6) are able to defecate without enemas and in 62 per cent (n=10) enemas were absolutely necessary for achieving defecations. In all full continence for solid faeces was achieved.
Conclusions: The initial results with this technique have been encouraging. This technique proved effective in all patients thus treated and led to achievement of satisfactory neoanal continence. The Lasaro da Silva perineal colostomy is very easy to perform; results reproduced by different surgeons were similar. Because of the small number of cases larger studies are needed before its routine application in clinical practice.

Combined interventional radiological treatment of rectal tumours and their liver metastases

Z. Vigváry, E. Makó, Z. Tarján and D. Görög* *Dept. of Radiology and *Dept. of Transplantation Surgery, Semmelweis Medical University, Ulloi ut 78/a, 1082 Budapest, Hungary*

Aim: To assess alternative interventional treatment results for rectal tumours and liver metastases.

Materials and methods: Sixty-one patients with inoperable lumen restricting rectal tumours were treated with the combination of selective (ADM and/or MMC + Gelaspon) chemoembolization, intraluminal cryotherapy and LDR Cs-137 irradiation. The catheter was placed into the superior rectal artery or into the hypogastric arteries. In 29 patients having liver metastases additional selective hepatic artery chemoembolization was performed in altogether 55 cycles. For response assessment rectal and abdominal US and CT examinations were carried out. Survival times and quality of life were assessed.
Results: I. Rectal tumours: acute bleedings were stopped and tumour volume was reduced in all cases. CR: 0, PR: 36, MR: 23, P: 2. II. Multiple liver metastases (*n*=29): CR: 0, PR: 13, MR: 12, P: 4.
Conclusion: Combined chemoembolization, intraluminal cryotherapy and LDR CS-137 after-loading interventional radiological treatment proved to be efficient as a palliative treatment in inoperable rectal tumours and their hepatic metastases.

Cost-benefit problems in colorectal surgery in Hungary

I. Zöllei *Surgical Department of Albert Szent-Györgyi Medical University, Pécsi street 4, H-6720 Szeged, Hungary*

The costs of surgical procedures are increasing all over the world, because of new technical instruments and high salaries of surgeons and their assistance. That is a great problem in Hungarian hospitals, because the relatively low Hungarian GDP allows less and less budget for the hospital costs. The prices of instruments are well determined, but the prices of one hour's work in the operating room is not fixed even today in Hungary.

Clinical study was performed between 1 January 1990 and 31 December 1997. The goal of this study was to compare the perioperative data of patients with elective colorectal resections because of malignancies. The operator and the preoperative preparation of patients were the same. The patients divided into two groups. One part of them had operations with colon-anastomosis, the other with rectal anastomosis.

Data of 203 patients (105 female and 98 male) were analysed. One hundred and sixteen anastomoses were performed on the colon (68 of them were hand made and 48 were made by linear staplers). The rectal operations were divided into three groups. There was a group for patients with hand made anastomoses, a group for patients with anastomoses sutured by one EEA circular stapler, and there was one group for patients operated on with double-stapler technique. The groups were comparable. Distribution of sex, mean age and mean body weights were similar.

The mortality and complication rates were similar in the groups of patients with colon anastomoses. But the operative time was significantly shorter in the group of anastomoses made by linear staplers. Unfortunately the cost of operation was higher because of prices of linear staplers. The author could not determine how much cost was spared by the shorter operating time.

The mortality rates were similar in the groups of patients with rectal anastomoses. The complication rate was the lowest and the operating time was the shortest in the double stapling group. Unfortunately the cost of operation was the highest in that group because of the prices of two staplers. The author could not determine how much cost was spared by the shorter time and the lowest complication rate.

Our experience in complex treatment of thyroid carcinoma

A. Atanasov, K. Kalinova, I. Ratshcov and D. Valtshev *Dept. of General Surgery, Medical Faculty of Stara, Zagora, Bulgaria*

Introduction: We have undertaken a retrospective review of all 19461 patients with different thyroid diseases operated in the period between 1967 and 1997. The patients were segregated into groups according to disease: 6344 nodular goitre, 11820 multinodular goitre, 1297 Grave's disease. 6091 patients with nodular goiter with clinical and paraclinical symptoms of hyperthyroidism.

Methods and procedures: Thyroid cancer was found in 867 patients of department general surgery (4·4 per cent) – 791 patients with differentiated cancer/papillary carcinoma – 642 patients follicular carcinoma – 149 patients undifferentiated cancer in 27 patients, sarcomas – 2 cases and medullary carcinoma – 45 cases. In period of 1 to 4 years after operation all of patients with undifferentiated carcinoma and sarcoma died. In cases with differentiated carcinoma 3 patients died, and with madullar carcinoma 8 died.

Results: For all of patients with carcinoma were reserved surgery treatment (thyroidectomy), and during the last 3 years we performed organ-peserveted operation in case with differentiated carcinoma-patients without regional lymph node metastases underwent lobectomy, istmectomy and contralateral subtotal resection 193 patients underwent neck lymph node dissection for metastases. These patients were not treated with radioiodine therapy. In cases with undifferentiated carcinoma we performed thyroidectomy with lymph node dissection.

Surgical treatment of secondary hyperparathyroidism in patients with kidney substitution therapy

M.Ł. Barczyński, M. Barczyński, S. Cichoń, J. Kopeć, F. Reś, M. Słowiaczek and W. Sułowicz *III Katedra i Klinika Chirurgii Ogólnej CM UJ ul. Prądnicka 37 Kraków, Poland, Tel. (048-12) 6331995, Fax (048-12) 6333105, E-mail: Marcin_Barczyński@mp.pl*

The aim of the present study was to evaluate the usefulness of surgical treatment in patients with secondary hyperparathyroidism.

Material and methods: Between January 1990 and July 1997, in 15 chronically dialysed patients and in three patients after renal transplant manifesting secondary hyperparathyroidism symptoms surgical treatment was performed. The diagnosis was based both on the estimation of levels of PTH, total and ionized calcium, phosphates, alcaic phosphatase in blood, and imaging procedures like ultrasonography and 99-mTc subtraction scintigraphy. The indications to surgical treatment were: obstinate ailments like generalized prurigo, bones and joints pain and muscular weakness with no amelioration after pharmacological treatment.

Results: The main procedure was subtotal parathyroidectomy in 17 cases (94·4 per cent), its extent, however, was in each case determined during surgery, depending on the quantity and size of parathyroid glands found. In all cases the immediate intraoperative histopathological examination of resected tissues was performed. In 10 (55·5 per cent) patients resection of thyroid gland tissues was carried out due to goiter, among them in 1 (5·6 per cent) case occult papillar carcinoma in manifested transient hypocalcaemia with good response to pharmacological treatment. Good results of surgical treatment reflecting in both ailment withdrawal and the normalization of PTH and phosphates in blood were obtained in 16 (89 per cent) patients. In 2 (11 per cent) patients the ailments lessened but did not disappear.

Conclusions: Surgical treatment of secondary hyperparathyroidism by subtotal parathyroidectomy is efficacious and entails a low risk of complications.

Surgical treatment of goiter in elderly patients

S. Cichoń, M. Barczyński, A. Konturek, J. Gucwa, M.Ł. Barczyński, M. Słowiaczek and R. Anielski *III Department of General Surgery, Jagiellonian University Medical College, Prądnicka 37, 31-202 Kraków, Poland*

Aim: The aim of the study is to underline differences in goitre surgery of elderly patients.

Material and methods: Since 1984 till 1996 there were 4122 patients operated on for goitre in III Department of Surgery. Among them 161 (3·9 per cent) were 70 or more years old, 13 (0·3 per cent) were over 80 years old. The eldest patient was 95 years old. There were 135 women and 26 men in this group (female:male ratio=5:1). Duration of goiter development varied from two months to 50 years, and in 50 per cent of cases was longer than 10 years. In 30 cases (18·6 per cent) thyroid gland weighed more than 300 g. In 61 cases (37·8 per cent) it was endothoracic or substernal goitre. In 43·5 per cent of cases it was benign nodular goitre, but in 22·4 per cent of patients there were thyroid gland neoplasms. The most common in this group was anaplastic carcinoma of thyroid (41·7 per cent), the second one was follicular carcinoma (16·7 per cent). Seven patients (4·3 per cent) died in postoperative period, all of them operated for anaplastic carcinoma of thyroid. The most common complication was unilateral paralysis of vocal cord, which occurred in 7 cases (4·3 per cent).

Conclusions:

1. Thyroid surgery in elderly age does not carry significantly higher risk than in the other age group.
2. Goitre in elderly patients is significantly more often malignant.
3. Very often goitre in this group is localized substernally or endothoracally.

Long-term survival in non-functioning malignant neuroendocrine tumour of the pancreas metastatic to the liver: case report

A. Crucitti, A. La Greca, V. Antonacci, A. Antinori, C. Breccai, R. Masetti and P. Magistrelli *Department of General Surgery, Catholic University of the Sacred Heart, Rome, Italy, (Chief Department: A. Picciocchi)*

Introduction: Neuroendocrine tumours of the pancreas represent less than 0·5 per cent of all pancreatic tumours. Only in 15–45 per cent of cases are they are clinically 'non-fuctioning'; of these, 80–90 per cent are malignant. We report a case of non-functioning malignant neuroendocrine tumour of the pancreas metastatic to the liver, analysing the diagnostic and therapeutic challenges that these tumours determine.

Case report: K.G., white, male, 60 years old, with a history of epigastric pain, loss of weight, previous diagnosis of unresectable neoplasm of the pancreas and palliative chemo-immunotherapy (cisplatinum, ethoposide, α-interferon). Despite this treatment, progression of both primary tumour and metastases was observed. Eight months after first diagnosis, the patient developed nausea and vomiting and was then admitted to our Department. A huge mass was palpable in the upper abdomen with no clinical evidence of an endocrine syndrome. Patient assessment included: a CT scan, which confirmed a 20 cm mass arising from the body and the tail of the pancreas with multiple liver metastases, obstruction of the splenic vein and local venous hypertension; a coeliac axis angiography showing a complete obstruction of the splenic vein; meta-iodo-benzilguanidine (MIBG) and 111-Indium-pentetreotide scintigraphies, both negative; a dimercapto-succinil-acetate (DMSA) scintigraphy which showed a huge uptake in the upper left abdomen and in the liver. Plasma levels of islet cell hormones, histamin, serotonin and 5-HIAA urinary excretion were normal. A distal pancreatectomy with splenectomy, omentectomy, regional lymph node dissection and biopsy of an hepatic lesion was performed. The postoperative course was uneventful. Pathological report and immunohistochemical studies were consistent with a neuroendocrine neoplasm of the pancreas with lymph node and hepatic metastases.

Postoperative adjuvant therapy was administered: Cisplatinum + Ethoposide, 6 cycles; 5-Fluorouracil + Folinic acid, 4 cycles; octreotide, 1 mg per day, during the entire follow-up period. The patient is alive and fit 32 months after surgery with good control of the hepatic lesions and no signs of local recurrence on serial CT and US scans.

Conclusions: Non-functioning islet cell tumours are metastatic at the time of diagnosis in 80 per cent of cases. Somatostatin receptor scintigraphy improves the localization of both the primary tumour and metastases at the same time. However, with the most applied isotopes, either iodine-123-labelled octreotide or indium-111-labelled-DTPA (diethylene triamine penta-acetic acid) octreotide (pentetreotide), a significant rate of false negatives is observed. For this reason, recent studies have underlined the use of dimercaptosuccinil acetate (DMSA) scintigraphy. Besides imaging modalities, a differential diagnosis from a ductal carcinoma of the pancreas requires accurate immunohistochemical work-up. Advanced presentation does not preclude prolonged overall survival (35–63 per cent at 5 years). Therefore, aggressive surgical therapy is recommended whenever possible and pancreatic resection remains the treatment of choice both for cure and for palliation. Adjuvant mono- or multi-drug chemotherapy schedules have been tested with dismal results, while long-acting somatostatin analogues administered postoperatively seem to inhibit tumour growth.

Thrombo-embolic prophylaxis with low molecular weight heparine at endocrine surgical patients

K. Darvas, Zs. Molnár, P. Antony-Moré, I. Irtó, M. Tarjányi and J. Horányi *1st Surgical Department of Semmelweis Medical University, Üllöi ut 78, 1082 Budapest, Hungary*

Patients with endocrine surgical diseases of the adrenal gland are at high risk of thrombo-embolic complications because of obesity, cardiomyopathy, hypertension.

Of 21 patients operated for hormone active adrenal tumours thrombo-embolic prophylaxis were applied with low molecular weight (LMWH) heparine (enoxaparine, sandoparine). The diagnosis of the patients were Cushing syndrome of 9 cases, Conn syndrome of 7 cases and 5 cases of Pheochromocytoma. The type of operations were adrenalectomy in all cases. There were 18 women and 3 men, the age of the patients were 29–66 years (average 52 years). The indication of thrombo-embolic (TE) prophylaxis were varicositas of the lower extremity in 10 patients, obesity in 12 patients, cardiomyopathy at 7 cases and chronic bronchitis at 9 cases. There were 17 patients with two or more TE risk factors. The LMWH was applied 2 hours before operations once daily postoperatively for 7 days subcutaneously. The observed laboratory parameters were WBC, RBC, Hgb, Htc and platelet preoperatively and on the 5th and 7th postoperative days.

The Htc level changed from 0·41 to 0·38, the Hgb level from 14·1 to 13·8 g/l and the platelet level from 225 to 210×10^9/l. The changes of the laboratory parameters were non-significant, it was due to the operation and to the hemodilution. The side effects of the TE prophylaxis were pain at the site of the injection in two cases and mild local bleeding at the operation site in one case.

There were no thrombo-embolic complications in the perioperative period.

Our results were that LMWH is an effective preventive anticoagulant agent at high thrombo-embolic risk endocrine surgical patients.

Laparoscopic resection for pheochromocytoma: predictive factors for peroperative difficulties

L. de Cannière, L. Michel, E. Collard and J. Donckier *Mont-Godinne University (UCL) Hospital, B-5530 Yvoir, Belgium*

Laparoscopic approach is increasingly used for resection of adrenal lesions. We here report the difficulties we encountered during the resection of eight pheochromocytomas, in order to determine predictive factors for perioperative difficulties.

Material: Eight patients (median age 43 year: 12–70) presented with symptomatic unilateral pheochromocytoma (left/right: 4/4). All patients had complete endocrine workup, abdominal CT and MIBG scintigraphy. Preoperative phenoxybenzamine an intraoperative phentolamine plus labetalol were used for blood pressure (BP) control.

Results: All patients had their pheochromocytoma successfully removed by a transabdominal laparoscopic flank approach. The periadrenal fat was resected 'en bloc' with the adrenal lesion. Median lesion size was 4 cm (2–11 cm); median operative time 180 min (120–240); median blood loss 150 ml (20–800). Two complications occurred: one ischemia of the left kidney upper pole most likely related to clipping of an accessory upper renal artery, and bleeding in another patient having sustained, during the same laparoscopic operation, removal of a symptomatic 12 cm cyst of the kidney; bleeding was laparoscopically controlled. She was the only patient requiring blood transfusion.

Blood loss >400 ml and intraoperative hypertensive peaks (systolic BP >200 mm Hg) occurred in patients with highly secreting lesions (urinary epinephrine or norepinephrine levels 16 to 50 times above normal ranges) and in patients with lesions greater than 5 cm.

Conclusions: Laparoscopic adrenalectomy for pheochromocytoma is a safe approach but highly secreting lesions and/or with size larger than 5 cm lesions, seem to be the major factor for intraoperative haemodynamic instability and blood loss.

The dependence of surgical intervention extent on the morphological characteristics of thyroid cancer

I.S. Derizhanova and S.I. Sidorenko *Dept. of Pathology, Rostov State Medical University, Nakhichevansky 38, 344718 Rostov-on-Don, Russia*

The purpose of this investigation has been to work out recommendations concerning the extent of surgical intervention for thyroid cancer (TC) according to its clinicomorphological characteristics. The complexes (cyto- and histological, ultramicroscopic) investigation of 105 various forms of TC was carried out prior to, during and after operation. Attention was paid to the localization and number of nodes, their dimensions, the histological form and the differentiation degree, that was appreciated by points according to three morphological attributes (the percentage of the typical tumour structures to the total area of a neoplasm; the manifestation degree of cellular and nuclear polymorphism and the mitotic activity of a neoplasm). It was determined that the minimal extent of surgical intervention (hemithyroidectomy) is warranted in cases of highly differentiated papillary, follicular and C-cell tumours, which grow in the form of a single node with dimensions from 0·1 (microcarcinomata) to 4 cm; lympho- and haematogenous metastases are usually lacking. The extirpation of both lobes and isthmus of a gland with the revision of regional lymph nodes is imperative with the tumours of the medium differentiation degree, as there were noted multicentric growth in 46 per cent of cases and bilateral lesion in 23 per cent. Histologically these TC have more frequently papillary-follicular structure or conform to the diffuse-sclerotic version of the papillary TC. 34·7 per cent of patients of this group have metastases in the regional lymph nodes. The low differentiated tumours were characterized by diffuse multicentric growth, they often grow into the thyroid capsule and surrounding tissues. Histologically they are represented by amphicrine and combined tumours, preserving the signs of the A-cell and C-cell differentiation. With these tumours numerous lympho- and haematogenous metastases can be observed. In such cases, when treated by operative surgery, it is necessary to perform the extirpation of the entire thyroid gland and the nech fatty tissue with the lymph nodes.

The surgical treatment of hyperthyroidism – a review of 129 cases

M.R. Diaconescu, I. Costea, R. Danila and M. Grigorovici *IVth Surgical Clinic, 'Gr. T. Popa' University of Medicine and Pharmacy, 1 G. Ibraileanu Str., 6600 Iasi, Romania*

Aim: The authors provide a review of the personal experience and literature data in order to assess the role of surgery in the treatment of selected cases of hyperthyroidism.

Materials and methods: A retrospective study was carried out on 129 patients (121 female and 8 male, ratio f:m=15:1), with an age range from 17 to 78 years (mean=46 years), who underwent surgery for diffuse (Graves' disease) or nodular thyrotoxicosis (Plummer disease).

Preoperative diagnosis was achieved by physical examination, thyroid function tests, ultrasonography, thyroid scan and fine needle aspiration biopsy.

Results: Bilateral subtotal thyroidectomy was performed on 49 patients with Graves' disease as well as for 31 cases with toxic multinodular bilateral goitre. Forty-nine patients with unilateral nodular thyrotoxicosis underwent subtotal (or total) lobectomy.

Histology, performed by the same pathologist, revealed a case of papillary microcarcinoma associated with a toxic adenoma and the same lesion in a nodular recurrence, 10 years after a thyroidectomy for Graves' disease.

Transient postoperative morbidity consisted of 12 cases (9·3 per cent) of hypocalcemia and 5 cases (3·8 per cent) of dysphonia.

The long-term follow-up revealed 16 patients (12·4 per cent) with hypothyroidism, 5 cases (4·7 per cent) of hypoparathyroidism and 2 cases (1·5 per cent) of persistent recurrent laryngeal paralysis.

Conclusions: Surgery is a good, safe and rapid method of therapy for diffuse or nodular thyrotoxicosis, allowing the most certain road to euthyroidism and fewer long-term complications than any other treatment currently available.

Clinical experience in Hurthle cell tumours

F. Francomano, L. Napolitano, P. Scipione, F. Savini,
G. Bajocchi and D. Angelucci *Department of Surgical Pathology, Chieti University, SS. Annunziata Hospital, 66100 Chieti, Italy*

The World Health Organization Committee for the Histological Typing of Thyroid Tumors designates Hurthle cell tumours as a variant of follicular tumours but many authors do not agree with this decision because they believe that the clinical behaviour and the prognosis of these neoplasms is dependent more on the presence of Hurthle cells than on this histologic pattern.

There is also a strikingly remarkable difference in the prognosis reported in several series. This difference probably may be explained by the difficulty to distinguish benign tumours (adenomas) from the real malignant Hurthle carcinomas.

In the period 1987/97 six patients with Hurthle cell carcinomas and four patients with Hurthle cell adenomas underwent primary surgical treatment at our Institute (8·1 per cent of all thyroid carcinomas).

The diagnosis of Hurthle cell tumour was based on the presence of more than 75 per cent Hurthle cells and the malignity on capsular or/and vascular invasion.

All the patients with Hurthle cell cancer underwent total thyroidectomy and three with Hurthle cell adenoma thyroid lobectomy, one total thyroidectomy.

Follow-up time ranged from 1 to 8 years after surgery (mean 4·5 years). There was no death and no recurrence.

We have studied the nuclear DNA content in Hurthle cell tumours: 3 adenomas were euploid and1 was aneuploid, 4 carcinomas were aneuploid and 2 were euploid.

The results in our study of the DNA content and nuclear DNA ploidy are not uniformly consistent enough to allow a distinction between benign and malignant neoplasms and to evaluate the prognosis but we must consider that the number of patients and the follow up are still too limited.

Diagnosis and treatment of differentiated thyroid carcinoma: our results

G.J. Ghanimé, F. Cordibo, L. Valbuena, A. de la Iglesia and
J. Machuca *Hospital Juan Cnalejo, Apartado de Correos 2313. C.P. La Coruña, Spain*

Objectives: To evaluate the diagnosis, surgical treatment, postoperative complications and the prognosis of the differentiated thyroid cancer.

Patients and methods: We reviewed retrospectively 224 patients operated for thyroid cancer between 1977 and 1997. Two hundred and four cases (91 per cent) were thyroid differentiated carcinoma, 12 (5·3 per cent) medullary carcinoma, 7 (3·1 per cent) anaplastic cancer. We evaluated the sex, age, diagnosis procedure, surgical treatment, complications and survivals at 10 years.

Results: Median age of differentiated thyroid carcinoma 44·9 years (13–76), 102 (68 per cent) were female and 48 (32 per cent) male. The incidence of papillary carcinoma was of 178 (76·4 per cent) and, for the follicular 23 (10·2 per cent). The median age for papillary carcinoma was 44·3 years (13–76), and for follicular cancer was 45·5 years (range 29–65 years). With regards to surgical treatment, total thyroidectomy was performed in 106 patients (70·6 per cent), subtotal thyroidectomy in 52 (21·3 per cent) and lobectomy in 8 (7 per cent). The most relevant complications were: injury of the recurrent laryngeal nerve: bilaterally 2 (0·9 per cent), and 6 cases (2·9 per cent) unilaterally. Permanent hypothyroidism was observed in 12 cases (8 per cent). Ten-year survival in papillary carcinoma were 149 (83 per cent) and follicular 17 (73·9 per cent).

Conclusions: Thyroid differentiated carcinoma is significantly more frequent in females. The age is relevant with regards to the prognosis, taking into account the fact that most of the deaths produced by papillary carcinoma occur in the over 40 age group. The prognosis is also determined according to the extent of the primary tumour. In the follicular case, tumours exhibiting moderate or marked invasion had the worse 10-year survival.

Modified intra-arterial calcium stimulation with venous sampling test for preoperative localization of insulinomas

U.J. Hesse, L. Defreyne, K. König, M.M. Lerch, Rottiers,
G. Feifel, B. de Hemptinne, B. Kramann and M. Kunnen *Dept. of Surgery, University Hospital, De Pintelaan 185, 9000 Gent, Belgium*

Background: To determine the accuracy and safety of a modified intra-arterial calcium stimulation with the venous sampling test (ASVS) for preoperative localization of insulinomas. Modification included stimulation with a fixed low dose of calcium gluconate, additional stimulation in the distal splenic artery, and no insulin sampling in the left hepatic vein.

Methods: In 10 patients showing biochemical evidence of organic hyperinsulinemia, 0·45 mmol of Ca^{2+} was injected into the gastroduodenal, superior mesenteric, proper hepatic, proximal, and distal splenic arteries during angiography. Insulin levels were measured in samples taken from the right hepatic vein before 30, 60, 90, 120, 180 and 300 s after Ca^{2+} injection.

Results: Insulin gradients with an increase of more than fourfold indicated direct tumour supply, two- or fourfold correlated with collateral, and less than twofold correlated with normal tissue vascularization. ASVS localized all the adenomas of the pancreatic head (n=3) and body (n=2) and two of four adenomas of the tail correctly, as confirmed by surgery. Two adenomas of the proximal pancreatic tail were erroneously localized to the body segment, but the fault was rectified by angiography. In one patient with a negative ASVS and without exploration, the diagnosis of insulinoma was revised.

Conclusion: ASVS with a fixed low dose of calcium gluconate is a highly accurate and safe method for preoperative localization of insulinomas. Sampling in the left hepatic vein can be routinely omitted. Additional stimulation in the distal splenic artery seems helpful in surgical decision making, but additional experience is needed.

Recurrent laryngeal nerve injury after thyroid gland surgery (risk factors)

R. Mahanoglu, M. Doganay, N.A. Kama, U. Gozalan, E. Kesici
and A.Z. Akat *Ankara Numune Hospital, 4th Department of Surgery, Ankara, Turkey*

Introduction: Since the thyroid gland has a close neighbourhood with vital organs and structures, thyroid surgery does require a special knowledge, skill and an exclusive experience. Thus, protection of recurrent laryngeal nerve during thyroidectomy operations constitutes an important part of surgery. From this point of view, we planned this study to investigate recurrent laryngeal nerve injuries and its causes after thyroid surgery, performed in our 4th Surgery Clinic.

Patients and methods: Between January 1990 and November 1996, totally 465 patients underwent thyroid surgery at this institution. From this population, patients having experienced recurrent laryngeal nerve palsy had been followed-up at least 12 months and evaluated retrospectively. The statistical analyses were assessed with Chi-square or Fischer's exact test. P-values were determined for univariate analysis. Multiple logistic regression test was peformed for multivariate model. $P<0·05$ values were accepted as significant.

Results: Male and female patient numbers were 53 (11·4 per cent) and 412 (88·6 per cent) respectively. Medigan age was 37·7 years (10–75). Totally, recurrent laryngeal nerve (RLN) palsy occurred in 12·2 per cent of patients. The permanent palsy was 2·5 per cent and the transient palsy was 9·7 per cent. According to the number of nerves at risk, the rate of RLN palsy was 1·1 per cent for subtotal lobectomy and 5·4 per cent for total lobectomy ($P<0·01$). According to the diagnosis; the permanent RLN palsy were 2·6 per cent for euthyroid goitre and 11·1 per cent for chronic lymphocytic thyroiditis respectively ($P<0·05$). In thyroid carcinoma, the permanent RLN palsy rate was 4·7 per cent ($P<0·0001$). In recurrent goitre the rate of permanent RLN palsy were 20 per cent ($P<0·05$). According to experience; the results of permanent RLN palsy in thyroidectomy operations, performed by experienced tream, was 2·6 per cent respectively. The results of less experienced team; the permanent was 2·4 per cent. According to preservation and observation of the RLN; the permanent RLN palsy rates was 1·4 per cent respectively in observed and presented nerves. In cases, which the nerve was intended to identify but could not be found, the permanent RLN palsy rates was 1·3 per cent respectively. RLN palsy was completely transient in unexplorated cases (6·6 per cent).

Conclusion: In order to decrease the rate of RLN palsies in Education Hospitals, the cases, such as total thyroidectomy, recurrent goitre, thyroid carcinoma, chronic lymphocytic thyroiditis, which have high risk of RLN palsy, are required to be operated by experienced surgeons. Residents of Surgery should be educated by experienced surgeons and the permission to resident for thyroidectomy operations should be kept for later periods of residency.

The hyperparathyroidism of transplanted parathyroid tissue

P.E.M. Müller, R. Peller-Sautter, P.O. Hartmann and F. Spelsberg *Martha-Maria Hospital Munich, Wolfratschauser Str. 109, 81479 Munich, Germany*

Introduction: The total parathyroidectomy with autotransplantation of parathyroid tissue in the forearm (TPX+AT) is established as a standard treatment for four-parathyroid gland disease beside of subtotal parathyroidectomy. The literature describes a hyperparathyroidism of transplanted tissue up to 30 per cent. This study investigates the patients with TPX+AT in the period 1982–1997.

Methods: After TPX+AT periodically the calcium blood concentration was determined; in cases of hypercalcemia the parathyroid hormone was measured. If hyperparathyroidism was detected, an ultrasonic diagnostic, occasionally a MIBI-scintigraphy was carried out. The indications for reoperation were identical to the first surgical treatment. Depending on pathological findings the parathyroid tissue was reduced in regional or general anaesthesia in several steps or only enlarged tissue was selectively removed. In some difficult cases the tissue was removed completely and cryoconservated tissue was retransplanted in cases of hypoparathyroidism after some weeks.

Results: From January 1982 to December 1997 a surgical treatment was carried out to 1882 patients (range: 8–90 years) with hyperparathyroidism. Eight hundred and three patients had a four-parathyroid gland disease (primary HPT (pHPT): n=334, renal secondary HPT (rsHPT): n=469). To 530 patients we practised a TPX+AT. In 6·0 per cent (n=29) a hyperparathyroidism of transplanted tissue occurred in the mean after 32 months (range: 3–168). In these cases and in 11 cases treated before in other hospitals we reduced the transplanted tissue, sometimes in several steps till reaching normocalcaemia. In two patients we detected after removing the parathyroid tissue at the forearm a fifth parathyroid gland at the neck or in the mediastinum. In three cases the transplanted tissue was enlarged as well as we found a fifth parathyroid gland at the neck. There were no complications of surgical treatment. The histology of the reduced tissue demonstrated in 17 per cent (n=5) a diffuse and in 83 per cent (n=24) a nodular hyperplasia of the transplanted parathyroid tissue.

Conclusion: The TPX+AT is a sufficient treatment of the four-parathyroid gland disease. In 1·8 per cent (n=6) of pHPT and in 4·9 per cent (n=23) of rsHPT a hyperfunction of the transplanted parathyroid tissue occurred. The treatment was without problems and without complications. There were no cases of malign degeneration of transplanted tissue.

Solitary metastasis of renal clear cell carcinoma in a follicular thyroid adenoma: case report and review of literature

T. Ratia, A. Rodriguez, A. López, A. González, P. Rodriguez, I. Lasa, M. Díez, A. Gutierrez and J. Granell *Dept. of Surgery and Pathology, Hospital Univ. Príncipe de Asturias, Campus Universitario, Alcalá de Henares, 28805 Madrid, Spain*

Introduction: Metastases of renal cell carcinoma (RCC) to the thyroid presenting as a clinically palpable nodule are uncommon and may cause clinical and pathological diagnostical difficulties. They can appear years after the primary RCC was resected or before the RCC has been detected; as they usually appear as a solitary 'cold' nodule in I-131 scans and may be confused with primary thyroid tumours.

Case: A 79-year-old white man presented a 5×4 cm solitary hetero-echogenic, partially intrathoracic nodule in the right thyroid lobe. Its size was not reduced after 6 months of TSH suppressive treatment. FNA showed follicular proliferation. He had a past history of radical left nephrectomy for a RCC 3 years earlier ($pT_2N_0M_0G_2$, clear cell subtype). No evidence of recurrence had been detected in his follow-up. A right thyroid lobectomy and isthmectomy were performed; an intraoperative frozen section study was negative for malignancy. The definitive histological report was: metastasis of clear cell renal carcinoma inside a follicular adenoma, there was focal infiltration of the capsule and another 2 mm foci of metastatic RCC cells was found in normal thyroid parenchyma; thyroglobulin immunohistochemical reactivity was present in the adenoma and normal follicle cells, and was absent in the clear tumoural cells. One year after lobectomy the patient remains well, without evidence of further dissemination of the RCC.

Discussion: The most common metastatic tumour to masquerade as a primary thyroid tumour is renal cell carcinoma. In our case FNA and frozen section failed in the identification of metastatic RCC. Cytological diagnosis of thyroid RCC metastasis has been reported: cytomorphology is complemented with cytochemical fat staining. Histological differential diagnosis is with primary thyroid tumours with clear cell features; characteristic of metastatic RCC are: multifocality, optically clear cytoplasm, sinusoidal vessels, and large amount of cytoplasmic glycogen and fat. Thyroglobulin immunohistochemical staining is useful but diffusion of this marker from entrapped follicles may result in absorption by RCC cells. Autopsy studies in general oncological cases report a 10 per cent incidence of metastatic thyroid disease. Melanoma and breast tumours are the most frequent causes (40 per cent and 21 per cent), but most of the clinically detectable thyroid metastases come from renal tumours. Many of the reported cases occurred in abnormal thyroids; alterations in blood flow in nodular thyroid has been related to that observation.

The prognostic significance of thyroid metastasis of RCC vary according to the different cases in the literature: survival ranging from 32 months to seven years after surgical exeresis, prognosis thus not appear to be as poor as for thyroid metastasis from other primaries. If the metastasis is solitary resection can be curative.

Conclusion: Solitary RCC metastasis must be considered in the differential diagnosis of a thyroid nodule, even when several years have passed after a nephrectomy for this kind of tumour. A correct diagnosis may lead to a curative surgical procedure.

Insular (poorly differentiated) thyroid carcinoma: report of two cases and review of the literature

T. Ratia, C. Blanco, A. Santana, A. Rodriguez, I. Lasa, F. Hernandez-Merlo, M. Díez, A. Gutierrez and J. Granell *Dept. of Surgery, Endocrinology and Pathology, Hospital Univ. Príncipe de Asturias, Campus Universitario, Alcalá de Henares, 28805 Madrid, Spain*

Insular thyroid carcinoma (ITC) is a rare form of poorly differentiated thyroid carcinomas (TC) arising from follicular cells occupying morphologically and behaviourally a place between the well differentiated and anaplastic TCs. Although arguable, ITC is viewed nosologically by WHO as a variant of follicular TC. ITC usually occurs in an older group than well differentiated TC, and it is an aggressive and often lethal tumour. Its incidence in the USA is very rare; more cases have been described in Italy and in Paraguay (about 70 cases reported in the literature). Proper diagnosis of ITC is specially relevant because its prognostic meaning.

Cases: Two cases of ITC were found among 63 cases of TC treated in our centre in a nine year period. *Case 1:* A 53-year-old white woman presented with a 5×4 cm hard, fixed solid nodule in the left thyroid lobe, the nodule was 'cold' in the isotopic scan, FNA showed follicular proliferation. Marked infiltration of the strap muscles by a hard tumour was appreciated in the surgical procedure. Frozen section confirmed malignancy and a total thyroidectomy was performed. Definitive histological diagnosis was: ITC. I-131 remnant ablation was undertaken one month after surgery (200 mCi). Local cervical recurrence and bone and lung metastases that concentrated I-131 were present 5 months after thyroidectomy. A cervical debulking procedure and tracheostomy was performed. Severe hemoptysis, and widespread metastatic dissemination caused death seven months after diagnosis. *Case 2:* A 46-year-old white woman presented with a 6 cm solid lobulated, rapidly growing, hard nodule in the left thyroid lobe. 'Cold' in the isotopic scan, FNA showed follicular proliferation. The histology of the left lobe disclosed the diagnosis of ITC. A total thyroidectomy was completed as a second procedure. I-131 ablation of remnants was undergone (100 mCi). Four years after thyroidectomy a serum thyroglobulin rose strikingly and a 4×5 cm solid mass appeared in the right pterygopalatine fossa; the ascending ramus of the right mandible was partially destroyed. I-131 scan showed a pathological uptake in the right pterygopalatine area, no lung or other bone deposits were shown. FNA was diagnostic for metastasis of a poorly differentiated TC. Two separated doses of 200 mCi of I-131 therapy have resulted in a complete remission.
Discussion: The diagnosis is based in microscopic features: presence of round or oval nests composed of small uniform tumour cells. The growth pattern is predominantly solid, but microfollicles containing colloid may appear. Mitoses are always present. Necrosis is frequent, as well as capsular and vessel invasion. There is immunohistochemical reactivity for keratin and thyroglobulin; not for calcitonin. Cytological diagnosis is difficult; the main cytological features of ITC are: high cellularity, necrotic background, low grade of atypia, nests, and cytoplasmic vacuoles. The insular pattern may result in misdiagnosis of medullary carcinoma and other neuroendocrine neoplasms. It may be also confused with anaplastic TC when the growth pattern is solid throughout.

Because its follicular origin, ITC may concentrate I-131, a feature useful for diagnostic and therapeutical purposes.

Prognosis of ITC is poor: in the largest series 60 per cent of the cases apparently cured by surgery developed recurrences, and about 50 per cent died because this tumour.
Conclusion: Radical surgical treatment of TC is indicated when an histological pattern of ITC is found in the surgical specimen. Its propensity for local recurrence and early distant metastases demands an exhaustive follow-up.

Fine needle aspiration biopsy in the evaluation of thyroid nodules

H. Uncu, Y. Aker, A. Sakarya and Y. Kaya *Celal Bayar Üniversitesi Hastanesi, Genel Cerrahi A.D., 45010 Manisa, Turkey*

The purpose of this study was to investigate the confidence of fine needle aspiration biopsy (FNAB) in the preoperative diagnosis of benign and malignant thyroid nodules.

FNAB cytology results were compared with histopathologic results of 57 patients with thyroid nodules whom were operated in the Department of Surgery, Manisa Celal Bayar University, Faculty of Medicine between January 1997 and December 1997.

The rate of inadequate specimens was 5·3 per cent. Five aspiration biopsies were positive for malignancy, and the diagnosis was confirmed histopathologically in two of them. Thus, there were three false positive cytology (5·6 per cent). Two of four patients with proven carcinoma had benign cytological diagnosis, a false negative of 3·7 per cent. The sensitivity, the specificity, the positive predictive value, the negative predictive value and the diagnostic accuracy of this method were determined as 50, 94, 40, 94, 90·7 per cent, respectively.

As a conclusion, FNAB can be used as an initial diagnostic method in the evaluation of thyroid nodules, but since the sensitivity and the positive predictive value are low, it is not suitable to decide the cancellation of the operation according to only benign FNAB results without using other diagnostic procedures.

Surgical treatment of suprarenal gland tumours: analysis of our own clinical experience

Z. Wajda, Z. Gruca, P. Dembowski, K. Sworczak and A. Łachiński *II Department of General, Gastroenterological and Endocrinological Surgery, Medical University of Gdańsk, 1, Prof. Kieturakis Street, 80-742 Gdańsk, Poland. Tel/Fax: 04858 3018775*

The aim of the study was the analysis of 127 patients operated on because of suprarenal gland hypertrophy and tumours in our Department during the period 1959–1994. The majority of the patients – [103 (81·1 per cent)] had been treated for hormonally active diseases. The remaiing 24 (12·9 per cent) for non-active tumours and most of them have been incidentally diagnosed. Amongst patients with hormonally active tumours 46 (36·22 per cent) suffered from pheochromocytoma, 14 (11·02 per cent) patients from Conn's syndrome, 5 (3·93 per cent) from virilizing tumours and 38 have had Cushing's syndrome or Cushing's disease. There were 27 operations for Cushing's disease performed in the 1960s and early 1970s.

Diagnosis and localization of adrenal gland lesions was based on clinical symptoms, hormonal studies, classical radiological investigations and recently using ultrasound and computer tomography.

The majority of the patients were operated on through the anterior transabdominal approach but now we prefer an approach through the twelfth bed of the rib.

Early results of surgical treatment of patients with adrenal gland tumours were good; late results were dependent on the histological type of the lesions.

Nodular goitre and thyroid carcinoma in children and adolescents in a moderate endemic goiter area (Lower Silesia)

T. Żak[1], T. Łukieńczuk[2], R. Wąsikowa[1], Z. Iwanicka[1], S.M. Bagłaj[3] and K. Sawicz-Birkowska *[1]Department of Endocrinology for Children and Adolescents; [2]1st Department, Clinic of Surgery; [3]Department of Surgery for Children, UM Wrocław, Poland*

The territory of Lower Silesia is still a region of moderate endemic goitre. It is known, that in iodine deficiency areas nodular goitre and thyroid cancer is frequently common. An epidemiologic survey on iodine deficiency goitre was carried out in Lower Silesia as a part of the Polish national programme in 1992–1993 and demonstrate high goitre incidence in the population of school children in the age group 7–12 years (29·1 per cent, in 0·7 per cent a nodular goitre). The urinary concentration of iodine was low in all the investigated children (56±38 mg/l). The aim of our present investigation was to ascertain the percentage of malignancy in nodular goiter in the observed in our clinic patients from the Lower Silesia region.
Methods: The examination included 56 children (12 boys and 44 girls) with nodular goitre treated in our clinic in the last 10 years (from January 1987 to December 1997), most of them after 1991. Age at diagnosis ranged from 7 to 18 years with a mean age of 14·5 years and male/female ratio of 1:3·7. In all the patients following investigations were performed: TSH, T_3, T_4, thyroid ultrasonography, fine needle aspiration biopsy and Tc_{99} scintigraphy of the thyroid. Most of the patients were euthyroid, two children demonstrated pressure symptoms. All the patients were transferred to the Clinic of Surgery for children, where an operation was undertaken. After the operation a substitution with L-thyroxine was applied.
Results: A nodular goiter was observed especially in the elder group (11–18 years), with a dominance of girls in comparison with boys (3·7:1). Thyroid nodules were observed mostly bilateral. Thyroid cancer was observed in seven children (12·5 per cent), mostly in a single nodule. The histological examination revealed following: in 29 children colloid goitre, in 3 children cystic-nodular goitre, in 15 – follicular adenoma, in 2 – fetal adenoma, in 6 – papillary carcinoma, in 1 – follicular carcinoma.
Conclusion: Our analysis shows that there has been a striking increase in the frequency of nodular goitres in the last 10 years, with a significant percentage of malignancy (12·5 per cent), mostly in a single nodule.

Evaluation of reconstructions performed in radical operations of the tumours of Vater's papilla

P. Árkossy, P. Tóth, I. Kovács and P. Sápy *2nd Department of Surgery, University Medical School of Debrecen, 4004 Debrecen, Móricz Zs. str. 22, Hungary*

Aim: One hundred and fifty-seven patients were operated on because of pancreatic head and periampullary tumours between 1 January 1992 and 31 December 1997. The authors evaluate the results of operations of 20 tumours of Vater's papilla. All of the patients had icterus preoperatively.
Material and methods: In the diagnostic phase abdominal ultrasound, CT and ERCP examinations were performed. In 13 cases pylorus preserving pancreato-duodenectomy were undertaken: nine cases of pancreato-gastrostomy, four cases of pancreatico-jejunostomy. There was one case of the Whipple type pancreato-duodenectomy. In six cases different palliative operations were performed.
Results: During the resection of the papilla of Vater it may occur that the soft, glandular pancreas does not hold the stitches. In these cases the anastomosis insufficiency is more threatening, which was detected in two cases in the group of pylorus preserving pancreato-duodenectomy.
Conclusions: The authors in the above mentioned cases use a special operative method: the distance between the anastomosis of the pancreatico-jejunostomy and the duodeno-jejunostomy is longer, that makes possible to execute a much safer drainage in cases of potential anastomosis insufficiency.

Antioxidant deficiencies in chronic pancreatitis

D.J. Bowrey, G.J. Morris-Stiff, M. Davies, G.W.B. Clark and M.C.A. Puntis *University of Wales College of Medicine, Cardiff, United Kingdom*

Background: Recent evidence has suggested that certain nutritional deficiencies, notably that of selenium, may play a role in the pathogenesis of pancreatitis.
Methods: Nutritional profiles were obtained from patients presenting with recurrent acute and chronic pancreatitis. Assessment included evaluation of serum albumin, calcium, phosphate, carotenoids, trace metals (copper, zinc, selenium), vitamins A and E and fatty acids. For each variable comparison was made with age and sex-matched controls.
Results: There was no significant difference between controls and patients with acute pancreatitis for any of the parameters assessed. Patients with chronic pancreatitis had evidence of nutritional deficiencies compared with controls (results shown in table). Values expressed are mean ± standard error.

	Controls (n=19)	Acute pancreatitis (n=12)	Chronic pancreatitis (n=12)
Age in years	56±19	50±11	48±11
Beta-carotene (μmol/l)	0·39±0·35	0·26±0·11	0·11±0·08*
Lycopene (μmol/l)	0·41±0·3	0·2±0·1	0·07±0·04*
Selenium (μmol/l)	0·76±0·13	0·72±0·27	0·41±0·15*

*P<0·05 chronic pancreatitis vs controls (one-way ANOVA)

Conclusions: Nutritional deficiencies affecting known antioxidants were identified in patients with chronic pancreatitis. Similar observations were not found for patients with recurrent acute pancreatitis.

Early endoscopic sphincterotomy and late elective cholecystectomy for acute biliary pancreatitis

M. Cardi, I.A. Muttillo, L. Amadori, A. Brandimarte, A. Barbarosos and A. Bolognese *I Istituto Clinica Chirurgica, S.S. Chirurgia Urgenza 3, Università di Roma 'La Sapienza', 00161 Rome, Italy*

Biliary pancreatitis is initiated by obstruction of the ampulla of Vater by migratory gallstones. Conservative treatment is successful in 60–70 per cent of the patients. However, biliary sepsis and other complications develop in the other patients, and mortality ranges from 15 to 50 per cent. The benefit of early endoscopic papillotomy was investigated in a series of 40 patients admitted and treated in our institution for acute pancreatitis. The diagnosis of biliary acute pancreatitis was done by means of HIDA biliscintigraphy, sonography, and CT scan and standard laboratory examinations. Of the 40 patients, 34 were of biliary origin while six were alcoholic. According to Ranson's Criteria 24 patients had mild and 16 a severe acute pancreatitis.

ERCP made within 48 hours from admission in all patients showed only GB stones in four patients, CBD stones in 11, GB+CBD stones in 16, no evidence of stones but a swollen papilla with signs of inflammation in three patients. Late elective cholecystectomy was performed in all patients between 15 and 34 days after endoscopic papillotomy. Complications occurred in four patients (10 per cent) after ERCP and in three patients (7·5 per cent) after cholecystectomy. In conclusion, from the results of our study, it seems that early endoscopic sphincterotomy and late elective cholecystectomy are safe and effective in the treatment of acute pancreatitis of biliary origin.

Diagnosis and treatment of cystic neoplasms of pancreas: our results

G.J. Ghanimé, L. Valbuena and C. Gomez *Hospital Juan Canalejo, Apartado de Correos 2313, C.P. 15080, La Coruña, Spain*

Aim: To evaluate our experience in managing cystic neoplasms of pancreas.
Material and methods: Retrospective review of 21 patients with cystic neoplasms of pancreas treated between 1979–1996. Clinical, histological, and treatment parameters were examined.
Results: Mean age 57 years (range 32–79), 15 females (71·4 per cent), and six males (28·5 per cent). The main clinical features were: abdominal and back pain: 13 (61·9 per cent); weight loss: eight (38 per cent); and palpable mass: five (23·8 per cent). In order of histological finding: serous cistadenomas: 11 (52·3 per cent); cistadenocarcinomas: six (28·6 per cent); and mucinous cystadenomas: four (19 per cent). Surgical treatment was performed for all patients; curative resection in 17 (80·9 per cent); and paliative procedure in four (19 per cent).
Conclusions: The preoperative determination of histological type of pancreatic cyst is very difficult. The surgical treatment is still the main form to manage this type of tumour. The survival for cystadenocarcinoma is still very poor.

The role of multivariate tumour marker analysis in the differential diagnosis of pancreatic carcinoma and chronic pancreatitis

L.Z. Horvath, L.E. Flautner, T.F. Tihanyi and *B. Schumann *1st Department of Surgery, Semmelweis Medical University, Üllői út 78, 1082 Budapest, Hungary; *BYK Bureau, Budapest, Hungary*

Aim: Differential diagnosis between pancreatic cancer and chronic pancreatitis is a great clinical dilemma in numerous cases. Pancreatic cancer is one of the most aggressive gastrointestinal malignancy. An early and exact clinical diagnosis can improve the outcome of the management of patients suffering from pancreatic carcinoma. Specific tumour markers for pancreatic cancer could play an important role in clinical screening.
Material and methods: CA 19–9, CA 72–4, CEA, TPA and AFP tumour markers were analysed with RIA technique in 162 cases (108 chronic pancreatitis, 33 pancreatic cancer, 21 cases of uncertain diagnosis). According to clinical symptoms and radiological examinations differential diagnosis could not be maintained between pancreatic cancer and chronic pancreatitis in 21 cases. Tumour marker levels were compared with intraoperative findings and with histopathological analysis.
Results: Combined multivariate tumour marker analysis detected significant increase in 13 of the 21 uncertain cases, while intraoperative fine

needle biopsy diagnosed pancreatic cancer only in 10 cases. In cases of chronic pancreatitis tumour markers were in normal range in 95 per cent (*n*=103). In cases of known pancreatic cancer tumour markers were significantly elevated in 90 per cent (*n*=30).
Conclusions: According to our results we can conclude that combined multivariate tumour marker analysis could become an important screening method in cases of uncertain differential diagnosis between pancreatic cancer and chronic pancreatitis. Preoperative knowledge of tumour marker levels can help to avoid operative mismanagement.

Analysis of mortality in acute hemorrhagico-necrotizing pancreatitis

M. Jesipowicz, S. Rudzki, J. Furmaga, J. Jesipowicz and J. Bicki
First Department of General and Transplant Surgery of Medical University in Lublin, 8 Jaczewskiego Street, Poland

Despite the introduction of new drugs, changes in operation methods as well as constant advances in intensive care mortality in acute haemorrhagic necrotizing pancreatitis (AHNP) is still very high. In the years 1980–1997 there were 161 patients operated on for AHNP. Most of these patients were operated on between 3 and 72 hours after admission because of symptoms of acute severe peritonitis. In the years 1980–1989 laparatomy, cholecystectomy and choledochostomy on a T-tube extended by peritoneal lavage and drainage was performed. From 1989 the repeated laparotomy and permanent lavage were introduced in our operative treatment. In all patients blocking of gastric and pancreatic secretion, parenteral nutritional support and antibiotic prophylaxis were applied. In our patients total mortality caused by AHNP is 49 per cent (79 patients). We observed the group of eight patients (10·13 per cent) died despite of early operation (laparotomy and lavage, or repeated laparotomy) and despite very intensive treatment. Median time of treatment of early death patients was 6 days. The second group of patients (71–89·87 per cent) died between 8 and 71 days, median time of treatment was 29·2 days. All those patients died because of developed multiple organ failure and sepsis. The first insufficient organ was the lung and the second kidneys. Median time of treatment of survived patients was 74·3 days and ranged from 24 to 129 days. On the basis of our material we observe decreasing of mortality from 62·1 per cent (46 patients) in the years 1980–1989 to 37·8 per cent (33 patients) in the years 1990–1997. In our experience early operation and application of repeated laparotomy and permanent lavage allowed decrease in mortality from 62·1 per cent to 37·8 per cent.

Is gastric tonometry a good monitoring method in acute pancreatitis?

G.C. Kovács, Gy. Orgován, L. Fekete, *J. Fürész and †J. Regöly-Mérei *Surgical Department, Central Military Hospital, Budapest H-1134, Róbert Károly krt. 44, Hungary *Military Medical Research Institute of Army, †Third Department of Surgery, Semmelweis Medical University*

Aim: To acquire information about the splanchnic perfusion by the use of gastric tonometry in the early phase of acute pancreatitis (AP).
Background: Gastric tonometry is an accepted method to follow changes of tissue microcirculation and tissue oxygenation in the splanchnic region. Blood extravasation, diarrhoea, and paralytic ileus all lead to hypovalaemia and shock during the early phase of AP. Also splanchnic blood flow reduction caused by hypovolaemia is disproportionately higher than it is in other regions.
Method: Patients suffering from AP were monitored by gastric tonometry for three days starting immediately at the beginning of their hospitalizations. Routinely used laboratory, and cardiorespiratory parameters were also investigated. The patients received standard treatment in the intensive care unit.
Results: More than 48 hours long intramucosal acidosis ($pHi<7{\cdot}35$) and elevated local mucosal pCO_2 ($pCO_2>55$ Hgmm) occurred in the patients only who developed necrosis of the pancreas, or multiple organ dysfunction syndrome (MODS).
Conclusions: Our initial data show the presence of long-term splanchnic bed hypoxia at the beginning of severe pancreatitis. Integrity of the gut mucosal barrier is compromised by the ischaemia, which is consequence of hypovolaemia and shock. Injured gut mucosa is of fundamental importance in the pathogenesis of MODS which is one of the most severe complications of AP. Splanchnic bed circulation monitoring may play a role in the prognosis and therapy of AP, but further investigations are needed with this method.

Evaluation of the surgical methods of pancreatic head and periampullary tumours

I. Kovács, P. Tóth, P. Árkossy and P. Sápy *Second Department of Surgery, University Medical School of Debrecen, 4004 Debrecen, Móricz Zs. str. 22, Hungary*

Aim: The surgical treatment of the tumours of the head of the pancreas and of the periampullary tumours are the same, nevertheless the pathological behaviour of the two groups of tumours are different. The aim of this retrospective study was the comparison of operative outcome, nutritional recovery and survival of patients who underwent standard Whipple pancreatoduodenectomy (WP), pylorus-preserving pancreatoduodenectomy (PPPD) and palliative therapy of these tumours.
Material and methods: In the period from January 1992 to 1998 we observed 131 patients with tumour located in the head of pancreas and 26 patients with periampullary tumours. These included 20 tumours originated from the ampulla of Vater and six from the distal common bile duct. Symptomatic pancreas tumours are diagnosed by ERCP, transabdominal ultrasonography and computer tomography. Facultative angiography, video-laparoscopy in combination with sonography and peritoneal lavage are providing important information about the spreading of the tumour to archive satisfactory palliation endoscopically or surgically. Tumour markers such as CEA, CA 19–9 and CA 125 were also studied.
Results: The operability rate was 35 (26 per cent) in pancreatic head tumours and 18 (69 per cent) in periampullary tumours. Considering 53 resections: 11 Whipple type operation, 35 cases PPPD and seven local excisions for tumour of ampulla the mortality rate was three (6 per cent). We found that elevated serum level of CA 19–9 is the most sensitive marker of all of the tumour markers of the malignant pancreatic tumours. After non-resectional treatment seven (7 per cent) patients died in the postoperative period. After resection postoperative complications were in 12 patients (22 per cent). Delayed gastric emptying was more common in the PPPD group resulting in longer hospitalization. In PPPD group there was a better nutritional recovery and also the increase of both body weight and serum albumin level. There was no other significant difference between the survival of WP and PPPD group, but we found much better survival in patients with periampullary tumour.
Conclusions: Improved surgical techniques and improved perioperative management together decrease the surgical risk. Our data provided many evidences about the advantage of PPPD in the patients with malignant periampullary and pancreas head tumours. There is not any difference between the survival rates of WP and PPPD but the long term results and quality of life much better after PPPD.

Surgical treatment of pancreatic pseudocysts associated with chronic pancreatitis

A. Magyar, L. Flautner, T.F. Tihanyi and I. Pulay *First Department of Surgery, Semmelweis University Medical School, Budapest, Hungary*

Chronic pancreatitis (CP) is a progressive degenerative inflammatory disease. The primary therapy in CP is symptomatic, but the intrapancreatic, intraductal morphological alterations may require non-operative interventions or surgery. Authors analysed retrospectively data of 1060 patients undergoing 1305 operations for pancreatic pseudocysts complicating CP between 1987–1996.

Results	Total drainage	Total resection	Primary resection	Subsequent resection
No.	1167 (84%)	148 (16%)	90 (61%)	58 (39%)
Preop.diab.mell	141 (12%)	37 (25%)	22 (24%)	15 (26%)
Preop. Icterus mech.	227 (19%)	21 (14%)	11 (12%)	10 (17%)
Pancreatectomy		16 (11%)	8 (9%)	8 (14%)
Head resection		46 (31%)	19 (21%)	27 (46%)
Distal resection		75 (51%)	52 (58%)	23 (40%)
Enucleation		11 (7%)	11 (12%)	0
Morbidity	78 (6·7%)	21 (14·2%)	13 (14·4%)	8 (13·8%)
Reoperation	30 (2·6%)	13 (8·8%)	7 (7·8%)	6 (10·3%)
/died/	/6+/	/3+/	/1+/	/2+/
Mortality	10 (1·03%)	6 (4·05%)	3 (3·33%)	3 (5·17%)
Hospitalization	7 days	10 days	8 days	12 days

Conclusions: The non-resective surgical procedures (ductal decompression, pseudocyst drainage) have good effect in the early period of CP. Pancreatic head resection is recommended in compression syndrome caused by the inflammatory mass. Total pancreatectomy is seldom indicated, only in cases of complete destruction of the gland. The early postoperative morbidity and mortality was not significantly higher after subsequent resections, although most of them were head resections.

Contrast-enhanced computed tomography as a prognostic indicator of sepsis in necrotizing pancreatitis

L. Napolitano, R. Cotellese and P. Innocenti *Department of Surgical Pathology, Chieti University, SS Annunziata Hospital, 66100 Chieti, Italy*

In acute pancreatitis sepsis is very common and in necrotizing pancreatitis (NP) it develops in up to 60 per cent. It is possible to distinguish two types of sepsis in NP: one progresses slowly and appears two or three weeks after the primary pancreatitis has subsided, the other occurs simultaneously with the initial onset of pancreatitis. In the first type of sepsis, it is very important to predict the onset of this complication before the appearance of its clinical signs. In fact if a patient survives the first clinical stage, infection is the predominant cause of death in the late stage. The purpose of the present study is to evaluate to what extent it is possible to predict the onset of septic complications by means of contrast-enhanced computed tomography. We have investigated 20 patients with NP where the CT documented a necrosis. In 10 patients the extent of necrosis was less than 50 per cent of the whole gland and in 10 the extension was more than 50 per cent. In the first group the sepsis developed in one patient, in the second group in nine patients. The CT was always performed 2–3 days after the onset of the clinical signs of pancreatitis, while the signs of severe sepsis appeared 2–3 weeks after the clinical and laboratory signs of pancreatitis had subsided. In these patients we had always the surgical assessment of an abscess interesting more than 50 per cent of the pancreatic gland. All these patients underwent necrosectomy, drainage and continuous lavage. There were five deaths. We believe that when an enhanced CT shows an extent of pancreatic necrosis more than 50 per cent it is almost sure that a sepsis will develop.

Pancreatic mucinous ductal ectasia

C. Neves, P. Coutinho, R. Ramos, F. Costa and T. Conrado *Department of Surgery, Hospital S. Francisco Xavier 1495 Lisbon Codex, Portugal*

A 40-year-old female was admitted to our emergency department with the diagnosis of non-biliary acute pancreatitis.

The serum calcium and the serum lipids were normal and the patient denied the ingestion of alcohol or any kind of medication.

The posterior imagiologic studies included abdominal ultrasound (US) and computed tomography (CT) revealed a dilation of the entire pancreatic duct, more accentuated in the distal half of the gland. The endoscopic retrogade cholangiopancreatography (ERCP) showed a normal biliary tract without stones and the attempts to cannulate the pancreatic duct were unsuccessful. The serum CA 19-9 was normal.

The patient was explored surgically and we found a very dilated distal pancreatic duct, filled with mucin, and documented it by intra-operative pancreatography. A distal pancreatectomy was done but as the frozen section analysis of the pancreatic duct margin showed a mucinous cystadenoma we completed the pancreatectomy – total pancreatectomy with preservation of the pylorus.

The final pathologic analysis of the specimen revealed a mucinous cystadenocarcinoma (T_1N_0), a mucinous cystadenoma and hyperplasia and dysplasia along the entire duct. Two papillae: one for the biliary tract and one for the pancreatic duct.

After one year of the operation the patient has no clinical or image evidence of the tumour.

ERCP induced acute necrotizing pancreatitis

M. Oledzki, M.I. Pirski and M. Łukiański *I Department of Surgery, Medical University of Gdańsk Debinki 7, 80-211 Gdańsk, Poland*

Aim: Evaluation of the surgical treatment in complications after ERCP diagnostic procedure.

Material and methods: In the years 1994–1997, 10 patients (nine female, one male) (41–75 years old) were treated in our department for acute necrotizing pancreatitis (ANP) and cholangitis as a complication of ERCP. Indications for ERCP were bile duct stones six cases, jaundice – two, tumour of papilla Vateri – one, dilatation of common bile duct – one. Surgical treatment was indicated in patients whose clinical state was getting worse and acute necrotizing pancreatitis was confirmed. Time period between ERCP and initial surgical treatment ranged from two to 14 days (average 4·7). All patients were treated by laparoscopy according to Bradley's method. This procedure was repeated from one to 16 times (average 7·6). Total mortality rate was 30 per cent (three patients) due to multiorgan failure. The most common complications were jejunal and colic fistulas two cases, hydrothorax, respiratory and renal insufficiency. Hospitalization lasted from 27 to 180 days. Two patients developed diabetes.

Conclusions: ANP is a rare complication after ERCP but because of very heavy course and the high mortality rate it should be considered while qualifying patients for this test. Open drainage and monitoring in intensive care unit are the treatment of choice in such cases.

Unusual type of encephalopathy in the course of severe haemorrhagic-necroticans form of acute pancreatitis

J. Panek and W. Drożdż *Second Department of Surgery, Jagiellonian University Medical College, 31-501 Cracow, Kopernika 21 str, Poland*

The aim of this study is the presentation of a 38-year-old woman with severe haemorrhagic-necroticans acute pancreatitis (SHNAP), who developed multiple organ dysfunction syndrome (MODS) and also had encephalopathy expressing as a flaccid paralysis of all extremities. The diagnosis was confirmed by the 10-fold rise of amylase activity in serum and urine and by the USG examination in which the extensive haemorrhagic-necroticans changes were founded in the pancreas. Also it showed the stones in the gallbladder. On the fifth day after the admission she was operated because of the increasing peritonitis and the development of MDOS. On the sixth day after the operation rapidly worsening of the clinical state of the patient was observed. The logical contact with her was impossible to obtain and flaccid paralysis of all extremities was observed. Neurological examination confirmed diffuse injury of the brain cortex as well as the brain stem. However, in performed computed tomography no changes in the brain were found. Seven days later the improvement of the clinical state was observed. The slight movement of the extremities were presented but the muscle tonus was still low without any pathological reflexes. The passive and active rehabilitation of extremities from the 14th day was applied. The extremities movement returned on the 82nd day after the beginning of the complication. She left the department after 128 days of hospitalization in good general condition and full activity.

In the recent years the introduction of antibiotics and various methods of aggressive treatment of the systemic effects of sepsis have allowed the patients to either recover or survive for a much longer period and gave enough time for the neurological complications to appear and be recognized. Since encephalopathy may occur early in the course of pancreatitis and sepsis, without direct infection of the brain and without consistent neurological changes, a reversible 'metabolic' mechanism is likely to be responsible for it. Also cytokines may directly affect the brain function. These substances cause capillary leakage, increase procoagulant activity and have direct effects on the tissue metabolism. Very important are also the changes within the lipids of the brain which are responsible for these kinds of complications. False neuromediators and neurotransmitters are another possibility.

Acute pancreatitis with hyperlipaemia and hyperglycaemia induced by alcohol abuse

J. Panek and W. Drożdż *Second Department of Surgery, Jagiellonian University Medical College, 31-501 Cracow, Kopernika 21 str, Poland*

We have presented a case of acute pancreatitis with hyperlipaemia and hyperglycaemia induced by massive intake of alcohol.
Material and methods: Seven men with diabetes were admitted to our clinic during emergency duty as an acute abdomen after massive alcohol intake. Samples of blood were drawn immediately after admission. One of the signs of hypovolaemic shock presented with low arterial pressure under 80 mmHg and weak and rapid pulse rate to 150 per minute. In all, on the basis of clinical, biochemical, ultrasonography and computed tomography examinations diagnosis of haemorrhagic-necroticans acute pancreatitis (HNAP) was established. In all patients developed life-threatening complications as a multiple dysfunction organ syndrome (MDOS).
Results: Clinical and biochemical characteristics of patients with acute pancreatitis:

Age (years)	Sex	Cause	S-Amylase (IU/l)	U-Amylase	WBC (G/l)	Glucose (mmol/l)	TGL (umol/l)	Insuline (ulU/ml)
37	M	Alcohol	280	622	12·8	41·0	7090	4·13
43	M	Alcohol	2269	47563	23·5	31·9	9010	5·87
36	M	Alcohol	11820	53835	14·2	15·8	4890	4·99
39	M	Alcohol	9800	23785	17·5	13·9	4230	3·85
36	M	Alcohol	11345	48766	14·9	12·8	3980	4·15
34	M	Alcohol	7655	23985	13·9	14·8	16440	5·16
32	M	Alcohol	3356	11825	14·7	15·9	3760	3·89

It seems that hyperlipaemia is regarded as a consequence of pancreatitis, but the development mechanism of hyperlipaemia due to acute pancreatitis has not been elucidated. In the development of diabetes mellitus, with excessive intake of alcohol as an evoking factor, triglycerides remarkably increase to present a state of diabetic lipaemia. Most commonly increase triglicerydes is in serum patients with Gram-negative sepsis. This situation is in severe HNAP. In this pathological state lipoprotein lipase activity decreases due to insulin insufficiency giving an increase of triglycerides in the blood. Alcohol decreases activity of lipoprotein lipase too. It may be a consequence of impaired clearance of triglycerides from serum. It is likely that hypertriglyceridaemia predisposed these patients to develop pancreatitis, alcohol being the precipitating factor.

Tumour necrosis factor alpha in the serum of patients with acute pancreatitis

J. Panek, M. Zembala, W. Drożdż and W. Lejman *Second Department of Surgery and Department of Clinical Immunology, Jagiellonian University Medical College, 31-501 Cracow, Kopernika 21 str, Poland*

This study was designed to examine whether the occurrence of an increased TNFα level in the serum was associated with two major clinical forms of acute pancreatitis (AP): oedematous and haemorrhagic-necrotizing.
Material and methods: For analysis 33 patients with AP were included. Diagnosis was based on the typical clinical presentation confirmed by ultrasonography, CT and an increased amylase in the serum and/or urine. For analysis patients were divided into two groups: A – with oedematous form of AP (22 patients) and B – with severe haemorrhagic-necrotizing type complicated by multiorgan failure (11 patients). Both groups received typical conservative treatment. Nine patients from the group B were operated on during first 2 weeks of hospitalization, five of them have died. On autopsy extensive necrosis of pancreas and the retroperitoneal space was seen. Blood was taken for analysis on admission and during the next three days. TNFα concentration was determined by ELISA (TNFα-EASIA, Medgenix, Fleurus, Belgium). Results were expressed as a mean ± SD (pg/ml) and the statistical differences between the groups were assessed by a non-parametric Cohran–Cox test.
Results: Measureable low values of TNFα (mean 28 pg/ml) were recorded in the serum of patients with oedematous AP (group A) and they remained essentially unchanged during follow-up. In contrast, significantly elevated TNFα (mean 491±312 pg/ml) was observed in patients with haemorrhagic-necrotizing AP (group B). It decreased only slightly during the observation period. The difference in the TNFα level between the groups was statistically significant ($P<0{\cdot}05$).
Conclusion: Serum TNFα levels are significantly elevated in patients with haemorrhagic-necrotizing, but not oedematous, form of AP and we wish to suggest that TNFα may be an important factor in the pathophysiology of this disease. The strategies aiming at the inhibition of TNFα production (e.g. pentoxifylline) or at its neutralization (e.g. anti-TNFα antibodies, TNFα binding proteins) may have a therapeutic value in the treatment of the severe form of AP.

Pancreatic exocrine function after acute biliary pancreatitis

E. Pareja, E. Artigues, R. López, R. Fabra, A. Vázquez, D. Bautista, F. Peiró and R. Trullenque *Service of General and Digestive Surgery, Valencia University General Hospital, Valencia, Spain*

Introduction: According to the Cambridge and Marseilles Symposia, functional recovery of the pancreas occurs after an episode of acute pancreatitis if the primary cause and complications of the disease have been eliminated. However, recent research has shown contradictory results, owing to the difference in diagnostic methods and the proportion of patients studied in relation to the etiologic factor and severity of the disease, as well as the differences in the test utilized. Subsequent studies show contradictory results.
Material and methods: Sixty-three consecutive patients with acute biliary pancreatitis were studied. Seventeen were men (27 per cent) and 46 women (73 per cent), with an average age of 62·3 years. Forty-five were minor cases and 18 severe. All subjects underwent cholecystectomy. During the acute phase, severity was evaluated following the Atlanta criteria as well as the existence of necrosis and its percentage by means of dynamic CT. During follow-up, pancreatic exocrine function was assessed one month and six months after the AP by means of Fluorescein Dilataurate (FDL). Chymotrypsin and Fat in faeces Tests; at one year after AP the Secretine-Pancreozimine Test (PSP) was carried out. The possible existence of pancreatic exocrine insufficiency following the biliary origin AP, as well as whether this possible deficit was related to the severity of the episode, was investigated.
Results: The study showed that our patients presented no deficiency in pancreatic exocrine function at one month, six months and one year after acute biliary pancreatitis. The statistical analyses carried out in order to assess the relationship between severity of the AP and the various pancreatic exocrine function tests demonstrated that there were no significant differences.

TEST Direct T-PSP	Mild (n=45)	Severe (n=18)	TEST Indirect T	SEVERITY Mild (n=45)		Severe (n=18)	
				1 month	6 months	1 month	6 months
Bicarbonate (mEq/1)	95·5±10·7	98±15·9	FDL	60·7±27·3	58·9±20·6	53·8±24·4	60·3±24·4
Chymotripsin (KU/60')	26·4±8·7	33·6±13·9	Chymotrypsin	10·4±5·9	12·8±7·7	13·3±8·4	12·3±6·8
Lipase (KU/60')	273·5±84·7	316±186·4	Fat in faeces	3·3±2·6	3·4±2·4	2·6±2·3	2·9±1·8

Conclusions: After the primary cause of the disease has been eliminated, pancreatic exocrine function reverts to normalcy following an episode of acute biliary origin, with no relationship between functional exocrine reserve and severity of the disease being observed.

Prophylactic of the purulent-septic complications on severe acute pancreatitis

A.A. Perejaslov, S.N Chooklin and T.G. Kazmirchuk *Department of Surgery, Medical University, Pekarska 69, 290010 Lviv, Ukraine*

The purulent-septic complications are one of the most important causes of death in patients with the severe acute pancreatitis. During 1990–1997, 73 patients with severe pancreatitis were treated Secondary pancreatic infection most likely occurs on 7–14 days after the onset of the disease Biochemical, immunological investigation was performed in all patients The fine-needle aspiration by ultrasonographic control was used for the detection of infected pancreatic necrosis. The aspirates analysed immediately by Gram stain, or taken for further analysis by culture The infected pancreonecrosis were observed in 29·4 per cent of patients The microorganisms causing pancreatic infection were shown to be common the enteric bacteria (*E coli* – 35 per cent, *Proteus* – 8 per cent, *Enterobacter* – 7 per cent, *Bacteroides* – 6 per cent and anaerobic flora – 6 per cent) These data pointed on that the some pancreatic infection in severe pancreatitis caused by translocated bacteria from the gut Development of the purulent-septic complications accompanied by the decrease of cortisol blood level (67·3 per cent of patients), the T-lymphocyte suppressors activity and the separation of cells in the immune response The increase of C3d level was detected in cases of purulent-septic complications Activation of the complement system cascade leads to the formation C3a, C4a and C5a anaphylatoxines, which increases the vascular permeability, stimulates the secretion of histamine from the must cells and basophils Macrophages stimulate the secretion of cytokines, such as TNF, IL-1, which create the additional effects of complement activation. The imipenem and ciprofloxacin were used for the systemic antibiotic prophylaxis These antibiotics had the most optimal pharmokinetics and antimicrobal spectrum for use in pancreatic infection The quick restoration of intestinal integrity (enteral nutrition, motility, biliopancreatic secretion) was another direction of prevention of bacterial translocation and, as the result, development of purulent-septic complications The administration of metoclopramid and prostaglandin E_2, with intestinal lavage was used for restoring of intestinal motility Applying of the pentoxyphilline and corticosteroids diminished the negative effects of cytokines. This management gave possibility decrease the number of pancreatic infections (17·6 vs 41·1 per cent of controls)

Possibility in diagnosis of pancreatic cancer

M.I. Pirski, J. Kostro, P. Witkowski and T. Draczkowski
I Department of Surgery, Medical University of Gdańsk,
Debinki 7, 80-211 Gdańsk, Poland

Aim: Evaluation of diagnostic procedures in pancreatic cancer
Material and methods: In the years 1994–1997, 100 patients, aged 36–91 (mean 63), with pancreatic cancer have been treated The most common symptoms were pain in the epigastric region (68 per cent), gastrointestinal disturbances (90 per cent), body weight loss (75 per cent), diabetes mellitus (37 per cent), jaundice (56 per cent), palpable mass (73 per cent) Period from the first symptoms until proper diagnosis was: one week – 1·5 years, and was shortest in the group of icteric patients Diagnosis procedures were carried out according to adequate protocol, which comprised of the following: standard and endocavital ultrasound, ERCP, CT and coeliacography. The most effective diagnosis method were CT and ERCP (90 and 84 per cent respectively) According to the UICC/TNM scale 45 patients were classified as stage I, 20 – II, 19 – III, 16 – IV. Intraoperative histopathological examination of wedge tumour biopsy and regional lymph nodes were carried out. When no cancer was found, multiple, thick needle biopsies (after first – 35, second – 8, third – 5) In two cases of negative intraoperative biopsy, cancer cell were found during regular histopathological examination
Conclusions: The majority of patients with pancreatic cancer are diagnosed too late to perform adequate treatment Our results suggest that CT, ERCP and needle biopsy are most effective in pancreatic tumour diagnosis

Pancreatic adenocarcinoma: a review of 85 cases

J. Sivestre, C. Herrera, M. Borrego, P Yunta, M. Meseguer, C. Sebastian, S. Carceller and S. Sancho Fornos *Servicio de Cirugía General I Hospital Universitario 'La Fe', Avenue Campanar 21, 46009 Valencia, Spain*

Aim: To evaluate the results of the surgical treatment of the carcinoma of the pancreas
Material and methods: We have operated on 85 patients of pancreatic adenocarcinoma during the period from January 1986 to December 1996. The location has been in the head in 79 per cent of the patients. The ag was between 28 and 85 years, with a 63·9 years average The 67·8 pe cent of the cases are included between the 60–80 years The treatment ha been surgical in all the patients, performing laparatomy in 10 cases (11· per cent); palliative surgery in 65 cases (76·5 per cent) and resectiv surgery in 10 cases (11·8 per cent), consisted of total duodenopancreatec tomy five cases and Whipple duodenopancreatectomy five. The palliativ surgery more frequent has been the choledochochoduodenostomy in 3 patients and the hepaticojejunostomy in 10 patients
Results: The operating mortality has been of 21·2 per cent (18 cases) Postoperative complications we have noticed in the 38·8 per cent (3 cases) being the most frequent the renal failure (four cases), the anasto motic leak (four cases), hepatic failure (six cases) and wound infection i seven patients The average length of stay has been of 17·6 days Th global survival rate has been of 15·8 months Concerning the technique, i the laparotomy the survival has been of 8·6 months, in the palliativ surgery of 16·3 and in the resective surgery of 21·2 months.
Conclusions: Poor improvement of the results in spite of the diagnost and therapeutics advances, earlier diagnosis should be sought The treat ment is always surgical The survival rate is around 18 months.

Oxidative stress dependent protein modification as a new signal for accelerated proteolysis in acute pancreatitis

Z. Sledziński, J. Antosiewicz, M Woźniak, J. Nowak and Z. Wajda *II Department of General, Gastroenterological and Endocrinological Surgery, Medical University of Gdańsk, 1, Proj Kieturakis Street, 80-742 Gdańsk, Poland*

Growing evidence points to free radical involvement in the pathogenes of acute pancreatitis (AP) This study aimed to investigate the protei peroxidation process in cerulein induced AP Eighteen rats were divide into three equal groups: in group 1 rats acted as controls, in group 2 an 3 rats had two intraperitoneal injections of cerulein 40 ug/kg for subse quent 3 or 6 h of induction period respectively Protein carbonyls whic reflect peroxidative damage was found to increase after 3 h, 2·53±0·4 vs 1·05±0·17 in control group and return to control level 0·95±0·04 afte 6 h These data suggest that during acute pancreatitis free radicals ma play an essential role in protein damage Decrease in protein carbonyl content after 6 h suggest an elevated proteolysis of oxidatively damage proteins.

Complete traumatic transection of pancreas

A. Slepavičius, A. Montvydas and N. Kaselis *Klaipeda Hospital, Liepojos 15, Klaipėda 5808, Lithuania*

Blunt pancreatic injuries are relatively uncommon, especially complet transection.

In our department eight patients underwent surgery for blunt pancreati trauma in 1997. The aim of this article is to study two cases of complet transection of neck (1) and head (1) of the pancreas.

The patient, male 31 years old, was admitted 3 days after the assaul complaining with severe pain in the abdomen. Peritonism was clear o admission The second patient, male 26 years old, was referred to ou hospital neurosurgical department 2 days after the assault from th regional hospital with traumatic cerebral coma (Glasgow 5) Compute tomography revealed the contusion of brain Diagnostic peritoneal lavag revealed blood in abdominal cavity Both patients underwent surgery hours after admission. At laparatomy retroperitoneal haematoma and packing haematoma in lesser sac was found. We mobilized the duodenum and entered the lesser sac. The complete transection of the head on the first case and the neck of pancreas in the second case was found. Acute traumatic pancreatitis was clear with peripancreatic infiltration in both cases. No more abdominal injuries were found. Distal pancreatectomy with splenectomy in the first case and without splenectomy in the second case was performed.

Only 10 per cent of pancreas was left in the first and 20 per cent in the second case. The first patient developed pancreaticocutaneous fistula, which closed spontaneously. He was discharged home on day 32 after the surgery without diabetes, but developed exocrine insufficiency.

The second patient died on the fourth day after the surgery because of the multiple organ failure and cerebral injury.

In conclusion, survival of patients sustaining blunt pancreatic trauma correlates with associated injuries, early recognition of lesion and choice of treatment.

Hepatic growth factor (HGF): a new marker for prognosing severity in acute pancreatitis

E. Tagliaferri, M. Secchi, E. Peralta, J. Scrigna, L. Quadrelli, M. Brogliatti and L. Rossi *Unit of Surgical Research, Hospital Italiano and Hospital Provincial, Rosario, Argentina*

Aim: Serum hepatic growth factor (HGF) levels are elevated in patients with acute and chronic liver disease. Production and release of HGF may be seen in liver and other organ failure, because it is a potent and generic tropic factor. We designed this study in order to analyse the predictive value of HGF in Acute Pancreatitis (AP).

Material and methods: During 1997 we performed a prospective trial in 20 patients with certified AP of any aetiology. Severity was determined with an Original Index and Apache II. Pancreatic complications were detected by dynamic CT Scan. Serum levels of HGF were determined at admission and every day before surgery in normal patients and, in patients with AP, an enzyme-linked immune assay.

Results: Serum levels of HGF in five control patients was 0·46±0·17 pg/ml. The mean value of serum HGF in the first day, in 18 patients with AP was 1·81±0·82 pg/ml ($P<0{\cdot}005$). In two patients with AP serum levels of HGF was 0·25 and 0·61 pg/ml, and minor values to 0·70 pg/ml were considered false negative (sensitivity was 90 per cent). In patients with severe AP ($n=3$) serum HGF levels were significantly higher 6·73±1·23 pg/ml ($P<0{\cdot}005$). Finally, serum HGF level decreased progressively during the first days of treatment, except in those patients who developed pancreatic complications.

Conclusion: We demonstrate that those serum HGF levels are elevated in patients with AP; they are also significantly higher in severe cases and in cases with local complications. Those preliminary results suggest that serum HGF levels may reflect the severity and prognosis in acute pancreatitis and that HGF may play a major role in the mechanism of tissue repair.

Microscopic bile examination (Meltzer-Lyon's test) in patients with idiopathic acute pancreatitis

J. Torres-Melero, P. Soriano, A. Reina, E. Vidaña, M. Ferrer, F. Suarez and R. Belda *Service of Surgery, Hospital Torrecardenas, Paraje Torrecardenas, s/no. Almeria 04009, Spain*

Introduction: Gallstones and alcohol abuse are the most important causes of acute and relapsing pancreatitis. In about 20 to 40 per cent of cases of acute pancreatitis, no cause can be found, and these are labelled idiopathic. The presence of microcalculi in the bile juice has been described as a cause of some pancreatitis initially called as 'idiopathic'.

Background: We present a microscopic study of bilis obtained by biliary drainage in patients who were admitted on various occasions for acute pancreatitis, in whom the etiology could not be clarified.

Patients and methods: During a period of two years, bile samples of patients with acute idiopathic pancreatitis were obtained approximately after two months of having suffered the pancreatitis episode. The technique used was based on Meltzer-Lyon's modified test. Findings obtained in the microscopic study were: liquid crystals of phospholipid-cholesterol, solid crystals of cholesterol monohidrate, granules of calcium bilirrubinate and microspherulites. Moreover, we show our results obtained after a cholecystectomy.

Results: During a period of 2 years, we studied 20 patients with acute pancreatitis who were treated in our Service of Surgery. There were 14 (70 per cent) women and six (30 per cent) men aged between 33 and 72 years old. We found cholesterol crystals in eight cases (40 per cent), calcium bilirrubinate granules were obtained in 10 patients (50 per cent), and two tests were negative. Sixteen patients (all with positive Meltzer-Lyon's tests) were operated, and a standard laparoscopic cholecistectomy was performed in all. The following results were obtained: microscopic colelithiasis in five, acute colecystitis in two, cholesterolosis in seven and without pathological findings in two patients. Two patients with cholesterol crystals were treated with acid ursodeoxicholic and one developed lithiasis macroscopic with biliary colics, therefore they were cholecystectomysed. After cholecystectomy no patient presented a new episode of pancreatitis. In the group with negative tests, one patient developed lithiasis by ECO and the other one is asymptomatic.

Conclusion: Microscopic examination of the bile juice is a risk-free technique that should be included in the study of the etiology of idiopathic pancreatitis, allowing an adequate treatment of these patients and decreasing their risk of new episodes of acute pancreatitis. Laparoscopic cholecystectomy is the surgical treatment of choice.

Necrotizing pancreatitis – progress and outcome according to a well established treatment protocol

N. Velitchkov, J. Losanoff, E. Anev, K. Kjossev and G. Kirov
Departments of Surgery and Medicine, Military Medical Academy, 1606 Sofia, Bulgaria

Aim: Severe pancreatitis still remains a challenge to surgeons. At present no universal guidelines as to the best treatment options exist. Therefore it was decided to study the progress and outcomes of the disease according to a well-established treatment protocol applied among a group of consecutive patients admitted to a single institution.

Material and methods: Between 1975 and 1997, 143 patients with severe necrotizing pancreatitis were investigated and treated at our institution. A universal operative policy was chosen consisting of open packing of the lesser sac combined with continuous postoperative sac lavage at a rate of 250 ml/hour and re-explorations on demand. At re-explorations, only obviously necrotic tissue was debrided and following this, continuous lavage was started again. It was stopped in the absence of progression of necrosis and the wound was left to granulate. Gastrointestinal complications were managed by resection and ostomy; and bleeding by packing and repeat explorations.

Results: The incidence of infection was 57·3 per cent ($n=82$). Of all, 32·2 per cent ($n=46$) developed gastrointestinal necroses with resulting fistula formation; 43·4 per cent ($n=62$) – other complications caused by pancreatic ductal disruptions and related sequelae. Infection and necrosis but not the surgical technique itself were found to determine the increased risk of complications. The mortality rate was directly related to the extent of necrosis, the total number of complications, and the presence of risk factors such as advanced age and chronic comorbid diseases.

Conclusions: Abdominal complications are common in necrotizing pancreatitis, especially when infection supervenes. They require a high index of suspicion, rapid diagnosis and prompt surgical intervention together with vigorous resuscitation both performed according to a well-established protocol.

Breast

Does the type of incision of the axillary node dissection influence in the frequency of postoperative seroma?

P. Armendáriz, I. Pérez-Cabañas, F. Domínguez-Cunchillos and M.A. Sanz *Hospital Virgen del Camino, Irunlarrea 4, 310084, Pamplona, Spain*

Aim: The seroma is the most frequent complication after axillary lymphadenectomy for breast cancer. When conservative treatment is used, the operation can be carried out by the same incision used for the resection of the mammary tumour or for an independent incision. The objective of our study was to evaluate if the fact that the incision is made in an independent way has influence in the frequency of axillary seroma.

Material and methods: We carried out a prospective study in which 109 patients operated consecutively of breast cancer were included. In 29 a mastectomy was carried out and they were excluded of the study. Of the remaining 54 the resection was carried out by means of two separate wounds and in 26 for the same wound. The number of dissected lymph nodes, days of drainage and frequency of axillary seroma in both groups were picked up. To compare the number of ganglion and the days of permanency of the drainage we employed a U-test of Mann–Whitney and to compare the seroma frequency a χ^2-square test.

Results: The data are exposed in the table. Seroma were significantly more frequent with a separate wound. No statistical differences were found for the other variables.

	Separate wound	Single wound
Seroma (%)	67	38*
Days drainage	6 (1–29)	4·6 (1–15)
Linfatic nodes dissected	18 (9–39)	18 (10–41)

*Statistically significant differences.

Conclusions: Axillary lymph node dissection through a separate incision increases the likelihood of seroma formation.

Lymphocyte subgroups in breast cancer and the effect of tumour removal

B. Ferruh, B. Semih, K. Savas, A. Semih and O. Serdar *Ankara University Medical School, Department of Surgery, 06100 Sihhiye, Ankara, Turkey*

Aim: Tumour behaviour is different among breast cancer patients. Though some prognostic factors have been defined, the cause of this difference is not clear. Alterations in host immune response to the tumour is a possible explanation. It is well known that some level of immune dysfunction exists in cancer patients. However, the effect of tumour removal on host immune function is not clear.

Material and methods: Fifty-one breast cancer patients who underwent modified radical mastectomy were studied. There were 12 patients with stage I, 16 with stage IIA, 13 with stage IIB and 10 with stage IIIA. The control group consisted of 20 women who underwent either thyroid surgery for benign causes or open cholecystectomy. Preoperative and postoperative (on the seventh day) blood samples were taken from the study and control group patients for flow-cytometric analysis. T lymphocyte, B lymphocyte, natural killer cell, T-helper, T-cytotoxic-suppressor, T active cell counts and T helper/T suppressor ratios were evaluated.

Results: T-cytotoxic-suppressor cells of the breast cancer patients were significantly higher than the control group ($P<0\cdot05$). Among the breast cancer patients T-helper cells were higher in early stages ($P<0\cdot05$). There was no differences between pre and postoperative lymphocyte profile in the control group. However, operation causes certain changes in the breast cancer patients. Postoperatively, B lymphocyte, T lymphocyte, T helper counts and T helper/T suppressor ratios increased ($P<0\cdot05$ for each). T-cytotoxic-suppressor ($P<0\cdot01$) and natural killer cell ($P<0\cdot05$) counts decreased.

Conclusions: The difference between the immune profiles of the breast cancer and the control group showed that antigenic stimulus of the tumour influences the parameters of the host immune functions. Operation had no effect in the control group, but had a certain effect in the breast cancer patients. Thus we believe that the removal of the tumour causes a considerable difference in immune parameters.

Axillary nodal clearance using minimal invasive techniques: axilloscopy: initial results

J.M. Abad, P. Besora, R. Claveria, J. Camps and X. Feliu
Hospital General D'Igualada, P. Verdaguer 128, 08700 Igualada, Spain

Introduction: Axillary dissection is considered essential to provide prognostic information, and effective in obtaining local control of breast cancer. On the other hand, axillary nodal clearance is controversial because of its morbidity.

Aim: To improve postoperative comfort and decrease complications such as wound pain or lower mobility of the shoulder. We have developed a new approach using a laparoscopic technique.

Material and methods: The first step is an incision in the fifth intercostal space (10 mm, mid-axillary line), blunt dissection and introduction of a balloon rod similar to that used for the extraperitoneal herniorrhaphy. Its insufflation induces a cavity to allow the insertion of a Hason trocar for insufflation (CO_2, 6 mm pressure) and introduction of the camera; a 5-mm and a 10-mm trocar are then placed for the regular laparoscopic instrumentation (scissors, endoclips and graspers). Dissection is carried out from the Latissimus Dorsi muscle till the thoracodorsal vessels are found and singled out, removing the axillary fat towards the chest wall, and releasing the axillary vein in all its trajectory. Subsequently, dissection is followed from Serratus Lateralis muscle until the Long Thoracic nerve is found; extraction of the axillary fat through the incision of Hason's trocar. The last step is the individualized dissection of level III preserving the Pectoralis Minor muscle, and extraction of the obtained fat by the 10 mm trocar.

Results: Seventeen patients have been enrolled in our initial experience. We did not have any conversion to open procedure. The thoraco-dorsal and long thoracic nerves and the innervation of the pectoralis major muscle were dissected and preserved. The number of axillary lymph nodes obtained were more than 13 in all cases.

Conclusions: Compared to open approach, the first results show that abduction, elevation and rotary movements of the shoulder are greater with the minimally invasive technique; arm circumference is lightly increased in open surgery. However, no significant differences have been observed. The postoperative comfort and cosmetic results have been excellent.

Factors affecting disease free interval in breast carcinoma

T. Coskun, G. Daglar, N.A. Kama, E. Reis, A. Yazgan and Y.N. Yuksek *Ankara Numune Hospital, 4th Department of Surgery, Turkey*

Aim: The duration of disease free survival following mastectomy is a matter of concern in the patients with breast carcinoma. It is a fact that some patients develop distant metastasis soon after mastectomy whereas the others have long disease free intervals. The purpose of this study was to determine the factors that affected the length of disease free interval in the patients with breast carcinoma.

Material and methods: Between 1992 and 1997, 72 patients with breast carcinoma underwent radical or modified radical mastectomy. Twenty-four of these patients developed distant metastasis following a disease-free interval of 2 to 53 months. The patients with distant metastasis were divided into two groups, based on the length of disease free interval: a) ≤16 months (14 patients); b) >16 months (10 patients). The comparability of the groups was assessed in terms of histopathological factors,

number of full-time pregnancies, age at first full-time pregnancy, body mass index (weight in kilograms divided by height in metres squared) and age. Mann–Whitney U-test and χ^2-test were used for statistical evaluation. $P<0.05$ was considered significant.
Results: There were no significant differences among the groups in terms of skin involvement, pectoralis major fascia involvement, nipple involvement, blood vessel extension, intralymphatic extension and tumour stage. However, the patients with short disease-free interval were significantly younger than the patients with long disease-free interval (≤40 years vs >40 years $P<0.05$) and more likely to have axillary tissue involvement ($P<0.05$), large tumours (2–5 cm vs >5 cm, $P=0.01$), more metastatic lymph nodes (1–3 lymph nodes vs ≥4 lymph nodes, $P<0.01$), and low parity (para <3 vs para ≥4, $P=0.01$). No significant difference was found between the groups concerning the length of survival time following the diagnosis of distant metastasis (mean 6·3 months vs 6·6 months, $P>0.05$).
Conclusion: The results of this study have shown that the patients with young age, axillary adipose tissue involvement, large tumour, increased number of metastatic lymph nodes and low parity developed distant metastasis earlier than the patients without these characteristics.

Surgical treatment of breast tumours

*A. Cucu, †A. Tudose, ‡G. Malene, *I. Iezan, *D. Cormos and *M. Constantin **Surgical Clinic III, †Oncology Department, ‡Pathology Department, County Hospital in Brasov, Bd. Bucuresti No. 31, 2200 Brasov-Romania*

Between October 1994 and November 1997 a continuous series of 115 patients (six men) with benign and malignant breast tumours was analysed. Breast cancer was found in 47 patients (one male). All the patients were included in an oncological and surgical protocol including initial evaluation and, if necessary, preoperative treatment (17 patients). Routine biopsy was made in all the breast tumours, the extent of resection according to the clinical stage of the tumour. Benign tumours were treated by lumpectomy or subcutaneous mastectomy. In breast cancers of stage I-II (29 patients), lumpectomy associated with axillary dissection were performed in 21 patients, while Madden mastectomy and axillary dissection in eight patients. In stage III (15 patients), lympectomy and axillary dissection were performed in three patients, the others benefitted from mastectomy and axillary dissection. Palliative mastectomy was made in stage IV (three patients).

Paraffin biopsy and axilliary lymph node status determined the oncologic protocol (radio-chemotherapy) in 40 patients who underwent surgery for cancer, seven patients were lost from follow-up; four patients deceased (three extensive metastasis and one stroke). The present study is limited in time.

Consequently, in advanced stages, conservative surgery can be performed, while in advanced ones oncological and surgical protcol must be extended.

Axillary adipose tissue involvement: a poor prognostic factor for breast carcinoma

G. Daglar, T. Coskun, N.A. Kama, U. Gozalan, E. Kesici and M. Guler *Ankara Numune Hospital, 4th Department of Surgery, Turkey*

Aim: The course of the breast carcinoma is still unpredictable today. Prognostic factors may help predict the patients for aggressive adjuvant therapies.
Material and methods: Between 1992 and 1997, 72 patients underwent radical or modified radical mastectomy for breast carcinoma and were followed up on for five years (range 2–60 months). The effect of age, menopausal status, blood vessel extension, intralymphatic extension, tumour necrosis, skin involvement, nipple involvement, involvement of pectoralis major fascia, axillary adipose tissue involvement, pathologic nodal status, number of involved lymph nodes, tumour size, T (tumour) category of AJCC-TNM staging and stage on survival were studied. Survival curves were calculated using the Kaplan–Meier method. Multivariate analysis was performed using the Cox's regression model.
Results: Of the 72 patients, five had stage I, 36 had stage II and 31 had stage III carcinoma. Forty-seven (65·3 per cent) patients were found to have axillary lymph node involvement: ten had 1–3 and 37 had ≥4 positive axillary lymph nodes. Thirteen patients died of their disease between 6–25 months after their operation. Of these patients, five (33 per cent) had axillary adipose tissue involvement. There was no death among the patients with stage I disease and one death (4 per cent) among the patients without lymph node involvement. Eleven patients are still alive with distant metastasis of the malignant disease. Of these patients, four (36 per cent) had axillary adipose tissue involvement. Seven characteristics were found to have a statistically significant prognostic effect by univariate analysis: (a) age; (b) axillary adipose tissue involvement; (c) tumour size; (d) T category of AJCC-TNM staging; (e) lymph node involvement; (f) number of involved lymph nodes; and (g) stage. When these seven characteristics were assessed by Cox's modelling, stage ($P<0.01$), number of involved lymph nodes ($P=0.01$), and axillary adipose tissue involvement ($P<0.05$) were independently related to survival.
Conclusion: The present analysis demonstrates that stage, number of involved lymph nodes and axillary adipose tissue involvement independently affected overall survival so that patients with advanced stage, ≥4 positive axillary lymph nodes and axillary adipose tissue involvement had a poor survival.

A clinicopathological study of a rare clinical entity mimicking breast carcinoma: idiopathic granulomatous mastitis

E. Yamac, V. Ali, K. Eray, O. Necmettin, K. Murat, O. Emin, Y. Rasih, E. Yıldız and O. Orhan *Ege University Medical School, Department of Surgery and Pathology, Bornova, Izmir 35100, Turkey*

Aim: Idiopathic granulomatous mastitis (IGM) is a rare chronic inflammatory lesion of the breast clinically simulating carcinoma. The purpose of this report is to review the clinicopathological features of this clinical entity in a series of 13 cases diagnosed in our institute.
Material and methods: The notes of the patients and the slides of the biopsy specimens of 13 cases with IGM were reviewed. Special stains for organisms and immunohistochemistry for T and B markers using the primary antibody was done. The diagnosis of IGM was made according to the criteria of Kessler and Wolloch.
Results: All but two patients were of reproductive age and all were parous. The main clinical finding was the unilateral, firm, discrete mass. All patients underwent excisional biopsy and recurrence was seen in three patients. In two of these patients who had recurrences, prolactin level was high and re-excision with antiprolactinemic therapy was performed. The third patient was treated by re-excision and oral prednisone. There was granulomatous inflammation, centred on breast lobules in all patients. T-cell domination was observed.
Conclusions: Exclusion of the other causes of granulomatous lesion is necessary to make the diagnosis of IGM. The treatment of choice is unclear. Because of clinical impression of a possible malignancy, surgical excision of the lesion is necessary. In patients with delayed wound healing or recurrence after excisional biopsy, or those patients who have had an incisional biopsy only, if prolactin level is normal, re-excision and oral prednisone usage will be curative. On the other hand, patients with high prolactin level who have recurrences, medical treatment to control prolactin level must be added.

Indications for different mammaplasty techniques

M. Geishauser, L. Kovacs and S. Schmiedl *Department of Plastic and Reconstructive Surgery, Klinikum rechts der Isar, University of Technology, Munich, Germany*

Over the last years a variety of new techniques of mammaplasty have been developed. Especially the techniques that brought a reduction of scars have readily been accepted and are routinely in use by now, like the short horizontal scar technique (Marchac) and the vertical scar techniques (Lassus, Lejour). Apart from a reduction of scars, these new techniques also were to bring better functional results, especially regarding perfusion, sensibility, motoric innervation of the nipple and the ability to breastfeed. This certainly enhanced the reliability and safety of the operation.

The attitude towards mammaplasty has changed, as some years ago most surgeons used only one or two techniques of the whole spectrum to perform all mammaplasties, irrespective of anatomical findings or the planned extent of reduction. Now, there is a variety of different methods of mammaplasty available which all have their specific indication and limitations. Thus, different indications need to be defined.

The periareolar mammaplasty is useful only for a very small reduction or a mastopexy. It is mainly reserved for a mere change of shape.

The techniques with vertical scar can presently be regarded as the standard method for resections amounting up to 800–1000 g per side, depending on the skin quality.

The techniques with L-, Z- or short horizontal scar may be used for planned resection volumes around 800–1000 g per side, which cannot be treated aesthetically by vertical scar techniques.

Inverted T-scar techniques remain the standard procedures for resections of more than 800–1000 g per side.

The definite choice of an operating method has to be made individually, considering anatomic findings as well as the planned size and shape of the breast. With further standardization, choosing the best technique for an individual patient will become simpler and clearer for the surgeon.

Using Sappey's anatomy for identifying sentinel lymph nodes in breast cancer

*K. Kett, *K. Szilágyi and †B. Anga **III Department of Surgery, University Medical School of Pecs, †Baranya County Hospital, Pecs, Rákóczi út 2, 7623, Hungary*

The most important prognostic factor of breast cancer is an adequate staging of the axillary lymph nodes, which influences both adjuvant and surgical therapy. Morton has successfully adapted the method that he had originally developed for identifying 'sentinel' lymph nodes in melanomas to the purposes of examining axillary lymph nodes in patients with breast cancer. Using this procedure he has also made staging simpler and more accurate. Due to the close relation between the plexus areolaris, the plexus subareolaris and the plexus periareolaris, the special lymphatic system of the breast makes it possible for the vital stain to be injected under the skin of the areola rather than round the tumour itself.

The axillary lymph drainage of 85 randomly selected patients with breast cancer was studied.

Of them, 55 patients underwent direct breast lymphography. For visualizing lymph vessels Patent blue dye was injected intracutaneously into the area of the areola. The lymph vessels and lymph nodes outlined on radiographic pictures after Lipijodol Ultrafluid was injected into a prepared collector lymph vessel. The dissection of axillary lymph nodes was started by preparing the lymph nodes that stained blue. The results were evaluated in a five-year follow-up examination.

In 30 patients sentinel lymph nodes were identified by comparing results yielded by the two methods. Patent blue was injected intracutaneously into the region of the areola, then, after the exposure of the axilla and the isolation of the blue-coloured lymph nodes Patent blue was injected around the primary tumour to induce the discolouration of further lymph nodes.

Our observations suggest that the procedure when the vital stain is injected into the plexus areolaris located in the region of the areola mammae is far simpler, as identical lymph vessels and lymph nodes get discoloured in the axilla.

In addition to its role in the identification of the sentinel lymph node, the vital stain injected into the skin of the areola signalizes lymph node metastasis by visualizing lymphostasis in the form of a pathological outline of the lymph nodes of the breast.

The data obtained in the 5-year follow-up suggest that the status of the axillary lymph drainage clearly indicates the likelihood of distant metastases and it can also account for the observation made by Gardner concerning the increased mortality rate of breast cancer in the first 7 postoperative years.

Can the mortality of breast cancer be reduced?

*D.B. Kingsmore, †D. Hole, †C.R. Gillis and *W.D. George
**University Department of Surgery, Western Infirmary, Dumbarton Road, Glasgow †West of Scotland Cancer Surveillance Unit, Glasgow, UK*

Aim: The mortality of breast cancer remains relatively unchanged by the therapeutic advances of the past 20 years. The aim of this study was to investigate the mortality curves of breast cancer and compare these with colorectal cancer.

Material and methods: All cases of breast cancer from 1980–1996 were identified and the pathological stage derived. Cause of death was determined from the Registrar General. The yearly proportional mortality (YPMR) due to breast cancer was determined by tumour size and nodal status. From an existing database of long-term follow-up of colorectal cancer with accurate stage, similar survival curves were drawn.

Results: The YPMR remained almost constant over a 10-year period of follow-up for tumours that were node negative, or less than 30 mm. This reflects a constant mortality rate which does not decrease with time. For larger tumours and node positive tumours there was a rise in the YPMR for the first 3 years which then tailed off. This curve resembles the curves of mortality from colorectal cancer, which show an exponential decay for each Dukes' stage.

Conclusions: The mortality for most cases of breast cancer is a continual constant ebb and any novel treatment will not show an improvement in mortality for many years. In addition, the optimal method of reducing the mortality will involve a stage migration to a better prognostic grouping, such as expected with mammography.

The disorders of peroxide-antioxide balance of an organism in breast cancer

B. Madej, E. Szpringer, L. Kurylcio, R. Maciejewski, Z. Wójtowicz, D. Górny, A. Stanisławek and E. Radzikowska
Department of Human Anatomy, Department of Pathophysiology, Department of Oncologic Surgery, Medical University of Lublin, 20-079 Lublin, Spokojna 1 Street, Poland

Introduction: Breast cancer is still the leading cause of cancer mortality in women. New diagnostic markers of the breast cancer are still being developed. The aim of this study was to estimate a peroxido-antioxide balance in breast cancer.

Material and methods: We analysed two groups of patients. The first group was 48 women with breast cancer. They were treated by modified radical mastectomy (removal of only the breast and the axillary lymph nodes). In the second one (the control group) there were 15 women, with diagnosis of benign dysplasia. They were treated by excision. The patients did not have other complaints. Assay of peroxido-antioxide balance was performed on the basis of lipid peroxidation products in plasma (MDA – malonyl dialdehyde, CD-conjugated dienes, HPETE-lipid hydroperoxide) and the activity of free radical scavengers, such as superoxide dismutase (SOD) in erythrocytes and glutathione peroxidase (Gpx) in whole blood. Conjugated dienes-CD and lipid hydroperoxide (HPETE) were marked using the method of Buege's and Augusta in Warda's modification. The concentration of malonyl dialdehyde (MDA) were determined using the method of Okava and Yagy. The activity of glutathione peroxidase (Gpx) were determined using method of Paglia and Valentine's and the activity of superoxide dismutase were determined using the Kawaguchi's method. In both groups above-mentioned markers were determined twice before surgery and 10 days after the operation. The results obtained were statistically analysed.

Results: The average age of patients was 49 years (range 33–68 years). In approximately 65 per cent of patients with the breast cancer the level of lipid peroxidation products was significantly higher before operation than after it. On the contrary the levels of superoxide dismutase (SOD) and glutatione peroxidase (Gpx) in approximately 70 per cent of cases were higher before the operation. In patients with a diagnosis of benign dysplasia, we have not noticed changes of the levels of lipid peroxides product and levels of SOD and Gpx. In the group of women with breast cancer there were statistically significantly higher levels of lipid peroxides and the levels of SOD and Gpx than in group of women with diagnosis of benign dysplasia.

Conclusions: Our results showed that: breast cancer increased the process of lipid peroxidation in an organism and increased of the activity of free radicals scavengers; the determination of levels of lipid peroxidation products and the activity of SOD and Gpx may be of considerable importance in diagnosis of breast cancer.

Correlation of biochemical tumour markers to conventional pathologic features in primary breast cancer

G. Péley, A. Bezzegh, I. Besznyák, I. Péter, O. Csuka, I. Számel, E. Farkas and B. Schumann *National Institute of Oncology, 1122 Budapest, Ráth Gy.u.7-9, Hungary*

The aim of our study is to analyse the relationships of conventional pathologic factors to serum and cell biochemical markers in breast cancer patients. A total of 574 patients were operated on for primary invasive breast cancer at our Institute from September 1996 to October 1997. The serum levels of CEA, CA 15·3, TPA-M and Thymidine Kinase (TK) were measured prior to surgery in all patients. Surgical specimens were processed for routine pathology (histological typing, grading and staging) and for cytosol analysis (oestrogen and progesterone receptors, p53 peptide, uPA, EGFr, erbB2, bcl2 and BAX determination). Disease relevant anamnestic and clinical data were also recorded.

Of the 574 patients studied, 63 per cent were node negative, 71 per cent postmenopausal, 88 per cent had tumour less than 5 cm in size (T_1-T_2). Estrogen receptor positivity was found in 61 per cent whereas progesterone receptor positivity in 72 per cent of the tumours. There were 95 cases (21 per cent) with histological grade I tumour.

The p53 protein and BAX levels correlated positively with tumour size, histological grade and lymph node state. The serum levels of CEA, CA 15·3, TPA-M and TK correlated with pathologic tumour stage. There was a significant difference in pre- and postmenopausal breast cancer patients in the serum level of TPA-M and cytosol level of BAX.

These results may give prognostic significance in breast cancer, but this needs to be proven by careful follow-up of patients included in the study.

Myxoid fibroadenomas of the breast

I. Pérez-Cabañas, F. Domínguez-Cunchillos, P. Armendáriz, M.A. Sanz and C. Yárnoz *Hospital Virgen del Camino, Irunlarrea 4, 31008, Pamplona, Spain*

Three cases of this rare entity which occurred in three young women of 36, 25 and 20 years of age are presented.

All of them consulted for palpable nodules with benign findings in breast ultrasonography and mammography. The fine needle aspiration cytology were informed as fibroadenoma. The reasons for the excision were: pain, big multiple nodules and familial breast carcinoma antecedent.

In two cases, the patients presented a facial multiple spotty pigmentation and one of them presented with ocular and labial pigmentation and an exotosis in the left parietal region (Carney's Syndrome). In this case the patient's grandfather had the same skin pigmentation.

An echocardiogram and a complete endocrine functional study were performed to the patients which were absolutely normal.

In 1986, Carney reported a familial syndrome transmitted as an autosomic dominant trait which consisted in spotty pigmentation of the face and oral mucosal, cardiac myxoma and endocrine overactivity. In 1991, he published myxoid changes in mammary stroma that were a specific pathological marker of a determined human genome.

This lesion is benign but it is important to recognize it because it may be associated to other grave syndromes as cardiac myxomas which are potentially lethal, so it is necessary to perform a thorough investigation of these patients and their families.

Breast conserving therapy in stage I and II breast cancer

Z. Rančić, L. Djordjević, M. Djordjević, R. Djordjević, M. Stojiljković, M. Jeremić, N. Djordjević, M. Pešić, D. Gmijović, M. Lazić, B. Marjanović and G. Stanojević *Surgical Clinic, Clinical Center, University of Niš, Yugoslavia*

The aim of our work was to compare effects of modified radical mastectomies (Madden, Patey) and breast conservation therapy on breast recurrence and overall survival.

Over the 5-year period from 1 January 1989 to 31 December 1993 at Surgical Clinic in Niš 142 women were treated for T_1 and T_2 breast cancer. Of the 142 women, 94 were treated by modified radical mastectomy and 48 had received breast conservation therapy. These women were separated into two groups. There were no significant differences between the groups in tumour size, incidence of axillary node involvement, histology grading ($P>0·05$). In general women treated for breast cancer with breast conserving therapy were younger, 42 years to 48 years treated by modified radical mastectomy.

Two of 48 patients had locoregional recurrence: one of them at the operation wound, the other elsewhere in the breast, histology was lobular type contrary to prior ductal carcinoma and was treated with radical mastectomy-modification of Madden.

Two of 94 patients who received modified radical mastectomy had locoregional recurrence: both of them on the chest wall.

The overall survival rates in modified radical mastectomy patients and breast conserving group were respectively 89·3 per cent and 91·1 per cent.

These results indicate that there were no significant differences between two groups in locoregional recurrence and overall survival in T_1 and T_2 breast cancer.

Breast reconstruction practice in the National Institute of Oncology, Budapest

Z.S. Révész, M. Kásler and G. Gulyña *National Institute of Oncology, Budapest, H-1525, Hungary*

In Hungary, breast cancer is the most frequent malignant disease of women. Reconstructive surgery plays an essential role in the rehabilitation of these patients. All reconstructive techniques are available at our Institute. Satisfactory cosmetic results can be achieved either by local, pedicled and free flaps or reconstructive expander and implant system. Their combination is also used if needed. Criteria of the surgery of choice are demonstrated. Future trends in reconstructive breast surgery are outlined.

Possibilities of conservative therapy in Paget's disease

A. Stanisławek, M. Mazurkiewicz, L. Kurylcio, J. Rzymowska and B. Madej *Institute of Oncology, 20-090 Lublin, ul. Jaczewskiego 7, Poland*

Paget's disease constitutes about 1 per cent of breast cancers (1) and its main characteristic is the occurrence of Paget's cells. From the point of view of biological growth the disease is divided into preinvasive form concerning only the nipple and invasive one spreading into the gland's parenchyma as well as from inside towards the nipple (epidermotropism). The accepted way of treatment is radical and total mastectomy, conservative operations being still controversial for many therapeutic centres. Our study comprised 28 patients treated in the years 1989–1994. Radical surgery was performed in 25 patients and conservative in three women. In 23 cases we had to deal with intraductal component and in three with infiltrating component of Paget's disease. Metastases to lymphatic nodes were observed in three patients. Five-year survivals amounted to 91 per cent in patients with intraductal component (2), 51 per cent in patients with infiltrating component (3) and in patients with lymphatic nodes metastases only 30 per cent (4). Local recurrences occurred in four cases after radical surgery, while after conservative operations in two patients. The first patient shown to have infiltrating components by histopathological examination, without metastases to the lymphatic nodes underwent telegammatherapy radiotherapy in whom a recurrence developed after 6 months. She underwent total mastectomy. The second patient was operated on repeatedly after histopathological detection of a large intraductal component and the presence of neoplasm within the surgical section. Radical mastectomy was performed in her. The last patient after conservative operation showed to have preinvasive form and has been under observation for 5 years. Conservative operations in Paget's disease should be performed in the preinvasive stage since the therapeutic and cosmetic effect is the best then.

Ulcerating breast cancer (UBC)

D. Stankovic, M. Miladinovic, R. Djordjevic, A. Kitanovic and V. Stankovic *Health Centre Krusevac, Department of Surgery, Krusevac, Yugoslavia*

The aim of this work is to show our experiences and results in UBC treatment.

In our Department, between 1988 and 1997, 478 (3·75 per cent) of radical mastectomy because of carcinoma of the breast. The patients with UBC were 52 (11 per cent) and they all have been surgically treated. Later on, 28 (54 per cent) of them were subjected to radiotherapy, and chemotherapy got 20 (38 per cent). 88 per cent were verified with present metastatic invasive ductal carcinoma changes in axillary lymphonodes. Twenty-four patients (46 per cent) were those who were only subjected to surgical treatment. Five patients (21 per cent) were living longer than 5 years; nine patients longer than 3 years (37 per cent) and over 1 year 17 patients (71 per cent). Twenty-eight patients (54 per cent) had radio- and/or chemotherapy where there were seven patients (25 per cent) who were living more than 5 years, 13 (46 per cent) more than 3 years, and 20 (71 per cent) longer than 1 year. All were female. Average age was 66 years and all of them were in postmenopause age. They were under review every 2 months regularly during the first year, and later on every 6 months.

From early postoperative complications we have seven wound infections which we solved by conservative methods.

Conservative postoperative treatment with our material has not had a decisive influence as to longer survival having in consideration about patients of older, wherein the only radical mastectomy gave good results.

Palpable breast masses: comparison of ultrasound and mammography in differentiating malignant and benign origin

Z. Tarján, G. Tóth, A. Kerpel-Fróniusz, H. Galgóczy, Z. Dömötöri and *B. Járay *Department of Radiology and *1st Department of Pathology, Semmelweis Medical University, Ulloi ut 78/a, 1082 Budapest, Hungary*

Aim: To compare High-resolution Ultrasound (US) and Mammography in differentiating palpable benign and malignant breast masses.

Material and methods: Two hundred and twenty-one palpable breast lesions of 120 patients aged 30–84 years were examined with X-ray mammography and high-resolution sonography. Benign or malignant characteristics of masses were established by both modalities. US guided FNAB was performed from all nodules and a 6–36 months follow-up was made for cystic lesions. The final diagnosis was obtained histologically for all malignancies. US and mammographic classifications were compared with the histologic diagnosis.

Results: Final diagnosis revealed 124 cysts (56 per cent), 30 carcinomas (13·5 per cent), 54 fibroadenomas (24 per cent), four benign phyllodes tumours, six mastopathic nodules, three fat necrosis. The malignant lesions included infiltrating ductal carcinoma (n=24, 80 per cent), infiltrating lobular carcinoma (n=3, 10 per cent), mucinous carcinoma (n=3, 10 per cent). Nineteen (63 per cent) of the malignancies had less than 2 cm maximum diameter. Sensitivities and specificities in diagnosing malignancies were not statistically significantly different for US (90 per cent, 81 per cent) and mammography (85 per cent, 95 per cent). US with FNAB yielded 100 per cent sensitivity and specificity in this study.

Conclusions: High resolution ultrasound is a comparable method to mammography in characterizing palpable breast masses, especially, if combined with US guided FNAB.

Cowden's Syndrome

U. Hakan, A. Yalçın, S. Aslan, K. Yavuz and Y. Osman *Celal Bayar Üniversitesi Hastanesi, Genel Cerrahi AD, 45010 Manisa, Turkey*

Cowden's Syndrome or multiple hamartoma syndrome is a rare autosomal dominant premalignant syndrome characterized by orocutaneous hamartomatous tumours, gastrointestinal polyps, abnormalities of the breast, thyroid gland and genitourinary system. The gastrointestinal polyps are generally benign and malignant transformation are seen very rarely. However, there are serious potential of malignancy in the breast and thyroid gland.

We present a patient with Cowden's Syndrome who underwent mastectomy operation 5 years ago with previously nondiagnosed Cowden's Syndrome in another centre. This patient was presented to our hospital with the complaints of anal fissure. After physical examination and investigations, the patient was diagnosed as Cowden's Syndrome. We found oral mucosal, gingival and cutaneous papillomas, gastrointestinal polyps, fibrocystic disease and malformation of the nipple of the other breast, and nodular goitre. It was learnt that her sister had died because of breast cancer.

If the physician remembers the Cowden's Syndrome in patients presenting with orocutaneous lesions, gastrointestinal polyps, thyroid and breast disease, it may lead to the early diagnosis and treatment of cancer.

A new concept in wound healing: the management of wounds with negative pressure therapy

P.E. Banwell, I.W. Holten and D.L. Martin *Queen Mary's University Hospital, London, UK*

Aim: We present the early results of a study evaluating the role of negative pressure therapy (NPT) in the management of various wounds. NPT is an exciting new concept in wound care which is simple to use and confers many benefits. It is claimed that it reduces oedema, increases blood supply, reduces bacterial colonization, promotes rapid formation of granulation tissue and mechanically closes the wound. Healing rates are dramatically improved. This study assesses these claims.
Material and methods: Two hundred wounds were treated with NPT, mostly as an adjunct to surgery, pre- and postoperatively. Both acute and chronic wounds were included in the study. Acute wounds included lower limb trauma, infected wounds, burns, necrotizing fasciitis, fasciotomies and pretibial lacerations. Chronic wounds included pressure sores, leg ulcers and miscellaneous non-healing wounds. All wounds were assessed clinically, photographed and mapped for size before and after treatment. Tissue samples for microbiology were obtained.
Results: Overall, the majority of wounds showed a marked clinical improvement including a decrease in size and a significant reduction in quantitative bacterial counts in infected wounds. The need for fewer dressing changes together with an earlier discharge had significant resource implications. We have found little morbidity in using NPT and patients tolerated the dressings with few problems. It appears to be patient, nurse and doctor-friendly.
Conclusion: This study has shown negative pressure therapy to be of great benefit in the management of wounds, particularly in problematic cases. The mechanism of action, future applications and its use throughout all surgical specialties is discussed.

Primary retroperitoneal tumours

A. Bedirli, N. Akyürek, M. Keçeli, O. Yüksel and M. Kerek
Erciyes University, Medical Faculty, General Surgery Kayseri, Turkey

Aim: The best treatment in primary retroperitoneal tumours is the total surgical resection of the mass. The most important postoperative problem is the recurrence of the disease.
Material and methods: Twenty-six patients with primary retroperitoneal tumours operated in our department.
Results: Eighteen (69·2 per cent) of the patients were male and eight were female (30·8 per cent), with an overall mean age of 43·3 years. The most frequent complaints were abdominal mass, pain, nausea and vomiting. All the patients were examined with ultrasonography (US), while 18 patients were examined with computerized tomography (CT). Four of the five patients who underwent needle biopsy under CT guidance had the diagnosis of maligant tumour. The intraoperatively measured diameters of the tumours were less than 5 cm in eight, between 5–10 cm in four and more than 10 cm in 14 patients. The histopathological distribution of the tumours among 26 cases were liposarcoma in six, leiomyosarcoma in four, malignant schwannoma in four, rhabdomysarcoma in three, angiomyosarcoma in two, chordoma in two, neuroblastoma in two, lipoma in two cases and teratoma in one case. Twenty-one cases (80·8 per cent) were malignant and five cases were benign in nature. Fourteen of these cases underwent total extirpation, while 12 cases had only biopsy of the mass. Among the postoperative complications, bleeding in four and lymphatic leakage in two patients were observed. One patient who had undergone only biopsy procedure died in the postoperative fifth day due to cardiac insufficiency (3·8 per cent). After the operation, one patient received radiotherapy, 10 received chemotherapy and seven patients received both. The 5-year survival rate was 57·1 per cent, while 3-year survival rate of the biopsied patients was 33·3 per cent.
Conclusions: The best treatment modality in primary retroperitoneal tumours is, if possible, total surgical resection. However, in our opinion, in cases of tumours not eligible for surgery, adjuvant treatment options combined with palliative resection procedures might increase the survival.

Total intravenous propofol anaesthesia (TIVA) with epidural or opiate analgesia for colorectal surgery?

F.G. Bergin, P.A. Mallinder, P. Royle and D.J. Leaper
Professional Unit of Surgery, North Tees General Hospital, Stockton-on-Tees, Cleveland, UK

Aim: To compare differing anaesthetic and analgesic techniques on perioperative outcomes of colorectal surgery.
Material and methods: In this prospective, randomized trial, 37 patients have so far been entered into four treatment arms. All received Propofol TIVA and either inaled nitrous oxide/oxygen mixture or air/oxygen. Preoperatively patients received either intravenous morphine or epidural bupivicaine, analgesia being maintained postoperatively as patient-controlled analgesia (PCA) or by continuous epidural infusion.
Results: Peroperatively, patients who had epidurals tended to have less operative blood loss (median 710, range 200–2235 ml) than the morphine group (median 1325, range 250–2725 ml) and fewer of them were transfused postoperatively (17 per cent vs 58 per cent; $P<0{\cdot}05$). Operating time was significantly reduced in patients having epidural (median 126, range 60–280 min) compared to the morphine group (median 180, range 86–240 min; $P\leq 0{\cdot}01$). Pain relief, measured subjectively (defined as excellent/good or fair/poor) was significantly better in those who had epidural (83 per cent vs 37 per cent; $P<0{\cdot}02$). Return of intestinal function was assessed by measuring days to return of bowel sounds, first flatus and first bowel action, with trends suggesting an advantage to the epidural group. The time from operation to discharge was less in the epidural group ($0{\cdot}1<P>0{\cdot}05$).
Conclusions: The use of epidurals in elective colorectal surgery is associated with a reduction in blood loss, transfusion requirements, shorter operating time, gives superior pain relief and may afford earlier return of intestinal function and earlier discharge from hospital.

Acute low intestinal obstruction due to AIDS-associated lymphoma

F. Burdío, A. Güemes, R. Palacin, J. Torcal, R. Sousa, T. Castiella and M.J. Palacios *Servicio de Cirugía 'A', Hospital Clínico Universitario 'Lozano Blesa', Avda. Gómez Laguna no. 15, 50010 Zaragoza, Spain*

Introduction: HIV-infected patients suffer different spectrum of diseases comparing with the general population. Non-Hodgkin's lymphomas appear when there is a profound immunodeficiency. In spite of the high incidence in our practice, it is unusual to find an acute low intestinal obstruction caused by AIDS-related lymphoma. Only short reports have been published about low intestinal obstruction (LIO) caused by Kaposi's Sarcoma, CMV intestinal infection and intestinal lymphoma.
Material and methods: This is a retrospective study of the patients suffering intestinal lymphoma that caused LIO. Since 1985 four cases of LIO were treated at our institution caused by AIDS-related lymphoma. Patients were divided into two groups (two patients each one) according to CD_4-cell count: group I <200/mm^3 and group II >200/mm^3. We studied clinical status (including Karnofsky's rate and survival rate), surgical procedures and pathological findings.
Results: Aged from 28 to 39 (mean 34), all of them were male. Three of them admitted homosexual practice, another intravenous drug addiction.

	Group I	Group II
Years from HIV-infection diagnosis	>4 years (4–10)	<1 year (1–4)
Karnofsky	<50%	>60%
Ag VIH	+	–
Survival from diagnosis of lymphoma	<1 month	>6 months with chemotherapy (CHOP)

All of them were operated to solve intestinal obstructions: two intestinal by-pass (two lymphomas of ileocal area) and two colostomies (two rectal lymphomas). Pathological study: two high-grade B-cell lymphoma, one high-grade T-cell lymphoma, one high-grade 'null' lymphoma.
Conclusions: 1. Survival rate was related to the CD_4-cell count and clinical status of these patients. 2. Chemotherapy can improve survival in selected patients. 3. Surgery is most often palliative (to solve intestinal obstruction).

The use of unilateral pudendal thigh flap in the treatment of complex rectovaginal fistula

A. Cardon, P. Pattyn, S. Monstrey, U.J. Hesse and B. de Hemptinne *Department of Surgery, University Hospital, De Pintelaan 185, 9000 Ghent, Belgium*

Introduction: A tissue transposition procedure is presented in which a unilateral neurovascular pudendal thigh flap is used to correct two cases of complex rectovaginal fistula.
Case reports: Case 1: A 49-year-old woman presents with a complex rectovaginal fistula caused by the prolonged use of analgetic suppositories in combination with corticosteroid enemas. Just proximal of the fistula there is a circular stenosis. A derivative colostomy is performed and two months later a unilateral pudendal thigh flap is performed. Anal dilatation is done twice before closure of the colostomy. No recurrence seven months later, no incontinence, no rectal dyschezia.
Case 2: A 27-year-old woman presents with a complex rectovaginal fistula after vulvotomy (narrow introitus). A unilateral pudendal thigh flap is performed without complication and without protective colostomy. Normal anal sphincter function and a normal introitus vaginae without recurrence after 10 months.
Operative technique: The fistulous tract is excised after an inversed T-incision is made in the posterior vaginal wall. The rectal mucosa and muscle are closed in sequential order. A large fasciocutaneous flap borne on a subcutaneous pedicle supplied by the posterior labial arteries and containing posterior labial branches from the pudendal nerve is tunnelled under the labium mayosa and rotated in the defect.

The causes of rectovaginal fistulas are multivaried but mainly caused by obstetric trauma. The rectovaginal fistulas are classified as simple or complex. Their treatment is based on this classification. Three mean approaches are possible: local repair, transabdominal repair and tissue transposition procedures. Simple fistulas are in general successfully treated by one of the local repair procedures. In complex fistulas abdominal procedures and tissue transposition procedures are recommended, mainly due to the presence of infected and poorly vascularized surrounding tissues resulting in poor wound healing.
Conclusion: The use of a unilateral pudendal thigh flap seems to be a successful and reliable alternative to treat complex rectovaginal fistulas. The flap is robust and sensate with a reliable blood and nerve supply.

Second primary malignancies: clinical approach and surgical results

R. Caronna, P. Chirletti, *F. Mauro, *M. Martelli, I. Cioe', D. Biacchi, Va. Stipa and V. Stipa *Surgical Pathology IX, Surgical Clinic I, *I Hematological Department, University of Rome 'La Sapienza', V. del Policlinico, 00161 Rome, Italy*

Aim: The main reasons for the growing incidence of second malignancies after primary neoplasms are the carcinogenic effect of antiblastic treatment, the widespread use of immunosuppressive drugs and the immunosuppression typical of chronic lymphoproliferative disorders. This study aimed to determine possible clinical and prognostic differences between patients with primary hematologic and primary non-hematologic tumours.
Material and methods: We studied 42 patients in whom second malignancies developed, in 16 cases after primary haematological and in 26 after non-hematological tumours. In both groups we assessed the pathologic stage of the first tumour at diagnosis of the second; the time elapsing between the two malignancies, the incidence of postoperative complications and survival.
Results: Hematologic tumour group: on diagnosis of the second tumour 62·5 per cent of patients had attained complete remission but 37·4 per cent had only a partial response or disease progression. A mean 4·5 years elapsed between the two malignancies. Staging identified second tumours in stages I–II in 56·2 per cent of cases and III–IV in 37·4 per cent; radical surgery, performed in 62·5 per cent of patients, led to 12·5 per cent morbidity. Overall 3-year survival was 31·2 per cent.

Non-haematological tumour group: on diagnosis of the second tumour all patients showed complete remission of the first tumour. A mean 6·6 years had elapsed between the two malignancies. Staging identified second tumours in stages I–II in 70·2 per cent of cases; radical surgery, performed in 61·5 per cent of cases, led to 15·3 per cent morbidity and 3·8 per cent operative mortality. Overall 3-year survival was 46·1 per cent.
Conclusions: Patients with haematological tumours have a shorter mean interval between the first and second malignancies; a higher percentage of second tumours in advanced pathological stages and shorter survival. These patients' less favourable prognosis seems to depend upon the high percentage of first haematological tumours uncured (about 40 per cent) and upon the severe persistent immune system defects. Although these defects are related to treatment they also closely reflect the biological features of the haematological malignancy (Hodgkin's or non-Hodgkin's lymphoma and chronic lymphoid leukaemia).

A contribution to the study of influential factors on postoperative malnutrition

E. Corbella Jacob, R. Pla Farnós and D. del Castillo i Déjardin *Department of Surgery of Pius Hospital of Valls and Hospital Universitari Sant Joan of Reus. Department of Medicine and Surgery, Faculty of Medicine, University Rovira and Virgili*

Aim: The surgical act, in spite of your curative intentions, behaves like an aggression, if this too intense or the biological response results inadequate postoperative complications appear. That this process will be favourable for the patient, the nutritional state that the patients present before a surgical intervention it is responsible to a large extent. In order to demonstrate the correlation between the operation and alteration of the nutritional parameters, it is necessary to identify nutritional and non-nutritionals factors, that could have a malnutrition prediction value.
Material and methods: Two hundred and six patients have being studied who interrelated independent variables have been used: nutritional parameters, age, sex, risk factors, type of pathology, treatments effected according to process, have been studied complications presented and other. Biochemical, anthropometric and immunological parameters, have been to include at the preoperative and postoperative stage of the patients. The obtained data allows the definition of the nutritional state of each patient.
Results: The presence of malignant disease, integrity of intestineal anastomosis, degree of operative contamination and age, present a relationship to of postoperative malnutrition. We have been able to prove the validity of the known predictors of morbidity and mortality postoperative. We have been obtained a forecast formula, to determine the greater surgical risk patients, in which intervene the following parameters: albumen, transferrin, cancer, and the degree of surgical contamination.
Conclusions: The nutritional state at with the patients arrives to the operation, has a great influence in the results. An important decrease in the visceral proteins in the postoperative period has been observed. Being at 48 hours postoperatively, the moment of minimum levels. At seven days recovery is observed. It is remarkable that neither anthropometric on immunologic parameters, take part in the forecast formula obtained by logistics regression that anticipates the degree of postoperative malnutrition. It is necessary to effect a nutritional preoperative valuation, that will warn us of possible postoperative complications and even leading to modification of timing of therapy.

The effects of early postoperative enteral feeding methods on immune system

D. Seher, M. Ufuk, E.A. Bülent and T. Atilla *Bilkent 2 Konutlari b2 Block No. 6 Bilkent, Ankara, Turkey*

In this study, the effects of early postoperative enteral feeding methods on immune system and the role of such methods in decreasing septic complications were investigated and compared to parenteral feeding methods in a population of patients undergoing upper gastrointestinal surgery. A total of 40 patients were divided into four groups each consisting of 10 patients and three groups were given different feeding methods. Patients who received previous chemo or radiotherapy, and those who had diabetes mellitus or malnutrition and those under immunosuppressive treatment were excluded from the study group. The first group received postoperative immunostimulant enteral formula, the second group received standard enteral formula, the third group received pronteral branched chain aminoacid solution in addition to standard dextrose and lipid solutions. The fourth group received no special feeding support and was used as a control group. Patients were followed up for signs of septic complications in the first 10 days of postoperative period (fever, ESR, WBC count, signs of wound infection, lung infection, peritonitis and sepsis). In addition plasma IgG and IgM, total lymphocyte counts, B lymphocyte counts, CD4/CD8 ration, T-lymphocyte and natural killer (NK) cell activities and plasma IL-2 levels were determined in the postoperative 1, 4, 7, 10th days.

The first and second groups had no septic complications but 20 per cent of the third group and 30 per cent of the fourth group demonstrated signs of septic complications. The first group had a higher T-lymphocyte count NK cell activity and IL-2 levels than second group and this difference was statistically significant. The first and second groups had a higher IgG, IgM, CD4/CD8, activated, T-lymphocyte count, NK cell activity and IL-2 levels compared to third group and this result was also statistically significant. The third group had higher IgG and IgM levels than fourth group but T-lymphocyte parameters did not differ significantly between the two groups. Septic complications were significantly lower in first three groups compared to control group. As a result early postoperative enteral feeding is superior to parenteral feeding methods and to control groups in terms of prevention of septic complications. Immunostimulants used in enteral feeding can improve immunological parameters although a significant clinical benefit has not been observed.

Management of a fulminant colitis in a neutropenic patient infected with human immunodeficiency virus (HIV)

J. de Tomás and *G. Olmedilla *Department of Surgery, *Department of Pathology, UG Hospital Gregorio Marañón, Doctor Esquerdo 46, 28007 Madrid, Spain*

Zidovudine (AZT) treatment induces neutropenia in human immunodeficiency virus (HIV)-infected patients, however, neutropenic colitis has been scarcely described in this group. Management of neutropenic colitis is a matter of debate, medical or surgical? Which is the timing for surgery? We present a case that illustrates such controversial and rare clinical situation.

A 38-year-old, heterosexual, non-drug abuser, HIV-infected, male with with mild neutropenia due to AZT therapy arrived at our hospital complaining of epigastric pain, temperature and vomiting without diarrhoea for 36 hours. He had started AZT treatment due to his low CD4+ cell count (200/mm^3) and 8 months before his colitis, he abandoned such therapy because of gastrointestinal intolerance and a neutrophil count of 900/mm^3. At hospital, the physical examination revealed a conscious patient with generalized abdominal discomfort, voluntary guarding without rigidity and tachycardia. On abdominal CT scan the most important finds were right colon thickening and free fluid. Neutrophil count was 456/mm^3 with a white blood cell count of 1200/mm^3. The patient was initially managed at the intensive care unit where a peritoneal lavage showed Gram-negative bacilli. Despite of broad-spectrum antibiotics and aggressive medical therapy, the patient got worse and was operated on 17 hours after his admission with coagulopathy and inotrophic support. A right hemicolectomy was performed due to caecal necrosis; unfortunately, the patient died 8 hours after. The histological examination of the specimen only revealed cocci and bacilli with no cytomegalovirus intranuclear inclusions.

Although abdominal examination of HIV-positive population is somewhat difficult, these, as oncologic neutropenic patients, belong to a high risk group to develop septic shock. Early surgical approach after a positive CT scan and peritoneal lavage confirmation of enteric bacteria by Gram dye could offer a better outcome among patients with neutropenic colitis. This is to our knowledge the second report ever in the literature of neutropenic colitis among HIV patients.

Is the surgical procedure the right approach for totally implantable venous device (TIVD) placement?

I. di Carlo, R. Lombardo, S. Puleo, A. Licata, G. Rodolico and G. Brancato *First Surgical Clinic, University of Catania, Catania, Italy*

Introduction: Totally implantable venous devices (TIVD) are frequently utilized in patients requiring prolonged intravenous therapy or repeated blood sample analyses. Percutaneous subclavian vein introduction is the method of choice but pneumothorax, or arterial puncture frequently occurs at moment of insertion.

Aim: To report our experience with surgical approach in order to assess the better way for TIVD placement.

Patients and methods: Data include TIVD inserted between November 1995 and November 1997. Age, sex, pathology, way of insertion, mean duration, intra and postoperative (until 30 days) complications of patients operated on were considered.

Results: During a 2-year period 122 patients were operated on for TIVD insertion. The patients were 75 males and 47 females aged from 29 to 79 years (mean age 59·5). One hundred and twenty-one TIVD were inserted for oncological reasons and one for TPN. All 122 TIVD were inserted by surgical procedure under local anaesthesia with small sedation, in 94 patients (77 per cent) by cephalic vein, in 13 (10·6 per cent) by axillary vein, in four by external jugular vein, in two (1·6 per cent) by internal jugular vein, in six by right gonadal vein, in one by coraco-brachial vein, in one by long saphenous vein and in 1 by vena cava. The mean duration was 456 days. No intra- or postoperative complications were recorded.

Conclusion: These results suggest that surgical procedure for TIVD placement is safe and reliable. Cephalic vein is the method of choice. Difficult vascular access may be utilized without any risk by experienced surgeons.

How clean are sterile instruments? parameters and testing and clinical data

Th.W. Fengler, I. Cramer, S. Kügler, M. Koschke and H. Martiny *Hygiene Institute, Free University Berlin, Germany*

Introduction: Bioburden in biofilms on surgical instruments cannot be detected if not visible. Data must be collected for cleaning modalities under the condition of complex filigran endoscopic instruments.

Material and methods: Different instrument parameters (surface, material, design, temperature, dry or wet test soil) were investigated in this project. Native blood as test soil seemed most adequate for comparison. It was recovered from surface by Sodium-dodecyl-sulfate (SDS) and the quantity of recovery (percentage) was analysed with the modified OPA-method.

Results: Cleaning performance was measured for clinical laparoscopic instrument cycles allowing to differentiate between working tip, tubes, handles. More than 95 per cent of native blood was regained from standardized test bodies. Significant differences in recovery could be determined for different surfaces of dental drills and non-dismantable arthroscopic instruments confirming the thesis that smooth surfaces and dismantability eases decontamination. The SDS/OPA method was sensitive, specific and reproducible.

Conclusion: *In vitro* testing to compare different models for test soils and laboratory methods of decontamination will be done next in this project as native blood is not suitable for daily routine in sterile supply. Validation of automated cleaning with washer/disinfectors depends on precise measurement of process parameters. More data about biofilms on frequently used instruments (arthroscopy, ENT, laparoscopy, neuroscopy, urology) must be obtained.

Extragonadal endometriosis: a non-anecdotic pathology for general surgeons

O. Fuentes, B. Narbona, L. Ochoa, R. Caparros, L M. Delgado, D. Gonzalez and B. Flores *Service of Surgery, Hospital de Poniente, ctra Almerimar s/n el Ejido 04700, Almeria, Spain*

Aim: Highlighting the importance that knowledge of the different clinical manifestations that extragonadal endometriosis may present for general surgeons.
Patients and methods: We present four cases treated for extragonadal endometriosis, from the 1698 (0·23 per cent) major surgery performed at our Service between March 1996 and December 1997.
Results: Cases 1 and 2 Two women, aged 42 and 46, who had undergone a caesarean, seven and 19 years earlier, respectively, presenting through palpable and painful tumours, mainly during menstruation, located beneath the scar from the caesarean In the first case, neither the US, the CT nor the fine needle biopsy cytology (FNBC) provided good diagnosis, whereas in the second patient, the clinical diagnosis was an irreducible laparotomic hernia Following the excision of the tumours, histological diagnosis revealed endometriosis in both cases

Case 3. Patient aged 31, with no gynaecological background whatsoever, who came to surgery complaining of a blueish umbilical tumour, which was painful and secreted blood during menstruation The FNBC did not prove conclusive, but the suspicion of endometriotic nodule was confirmed by histology following its excision.

Case 4· Patient aged 42, who had undergone a hysterectomy and a right salpingo-oophorectomy two years before and did not show any intestinal symptoms at all, she was operated for a tumour in the left ovary (confirmed by US and CT), with an extramucosa tumour then being detected in the sigmoid colon, hence a left salpingo-oophorectomy and sigmoid colectomy were performed. The histological result was ovary and intestinal endometriosis
Conclusions: Extragonadal endometriosis is a disorder with rather more than anecdotic frequency for general surgeons, with great clinical variations and for which the only certain diagnosis is by means of histological studies.

Occupational risk of intraoperative HIV-infection of surgeons in Ukraine

I. Gerych, I. Stoyanovsky and Vs. Vashchuk *Medical University, Lviv, Ukraine, PO Box 9881, Lviv 290038, Ukraine*

Rapid growth of the number of HIV-infected patients is observed today in most of the nations around the world and in Ukraine as well It is natural, that respresentatives of this contingent are more and more often admitted as surgical patients, considerably increasing the risk of contamination of surgeons.
Aim: Probability of intraoperative contact of Ukrainian surgeons with human immunodeficiency virus and the occupational risk of their HIV-infection was studied
Material and methods: I – Prospective study of the frequency of detected surgical glove damage (SGD) by way of postoperative polling among the surgeons using modified questionnary of Hussain (385 interventions) II – Determination of undetected SGD with the aid of air-immersion–water-submersion tests (330 surgical gloves after 55 randomly chosen surgeries) III – Determination of the risk of occupational infection of the surgeon as the result of probabilities of SGD while operating on the HIV-infected and frequency of seroconversion.
Results: Visible SGD have been reported by surgeons after 57 surgeries (14·8 per cent). Instances of occult perforation of the gloves of operating surgeon have been reported after 30 surgeries (54·5 per cent) Thus, total frequency of suboperative SGD appeared to be comparable with the numbers quoted in foreign literature (12–80 per cent) and attained 69·3 instances of failure per 100 surgeries According to our calculations ave
age statistical risk of intraoperative HIV-infection of the Ukrainian su
geon remained within the range of $8{\cdot}18 \times 10^{-7} - 1{\cdot}64 \times 10^{-4}$. The sam
index under the conditions of our clinic exceeded the national index b
185 times and attained $1{\cdot}51 \times 10^{-4} - 3\,02 \times 10^{-2}$ The reason for th
appeared to be a rather high percentage of parenteral drug addicts (13
per cent) among the patients in which clinical-immunological signs
HIV-infection have been found (32·8 per cent) In the event of exclusi
operation performed on the 'risk group' patients the probability of infe
tion of the surgeon increased by 7·5 times and attained critical values
$1\,14 \times 10^{-3} - 2{\cdot}27 \times 10^{-1}$.
Conclusions: The degree of probability of professional HIV-infection
surgeons is in direct proportion to the number of AIDS 'risk grou
patients operated on and the frequency of SGD occurrence. In order
prevent uncontrolled nosocomial spread of HIV-infection it is necess
to. 1) Promote HIV-awareness among the surgical teams and introduce
obligatory procedure of preoperative identification of the risk gro
patients; 2) Elaborate measures eliminating evident SGD and acciden
suboperative injuries of surgeons' hand and a system of the means
urgent prophylaxis of contact HIV-infection, 3) Elaborate reliable te
systems for timely detection of occult SGD; 4) Improve techniques
operative intervention in order to avoid intraoperative exposure of medi
staff to virotropic media of the patient.

Snake bites: effectiveness of antiviperin serum and surgery

M. González Penabad, F.J. Rebollo, M. López Bañeres, MaC. Juy
Rodrigo, A. Minguillón Serrano, *P. León Moreno and †E. Serra
Martinez *Obispo Polanco General Hospital, *Dr Peset Hospita*
†Genetic engineer, Av. Ruiz Jarabo 5, 44002 Teruel, Spain

Vipers inhabit all of the European Continent except for the North Po
However, the undoubtable epidemiological interest that represents its
ing, scientific papers are scarce. On the other hand, the use of antivipe
antidote remains polemic
Aim: To analyse our therapeutic results with a systematic administrat
of antiviperin serum.
Material and methods: In the last 10 years, 34 patients have b
accepted due to viper bites According to Wood-Parish classificati
stage 0 (4), stage 1 (6), stage 2 (20) and stage 3 (2) In 32 patie
antiviperin serum was administered (V. Aspis, V Berus, V. Ammodyt
in the first 24 hours Skin was infiltrated with 1 ml around the bite,
4 ml intramuscular injection At the same time, antitetanic and antibio
protection were administered. Neither wound infection nor mortality
seen. Surgery was only necessary in one case (stage 3) due to comp
ment syndrome affecting the left arm that needed fasciotomy of arm, fo
arm, wrist and second finger. Functional and aesthetic results were go
Conclusions: 1 – Antiviperin antidote used in an early phase, avoids
progression to advanced stages. 2 – Surgery is only necessary in so
cases like shown above.

Reduced amounts of total protein in artificial wounds of alcoh abusers

*†L.N. Jorgensen, H. Tønnesen, S. Pedersen, M. Lavrsen, J. Tuxøe, †Finn Gottrup and ‡C.F. Thomsen *Department of Surgical Gastroenterology and ‡The Alcohol Unit, Medical Department, Hvidovre Hospital, and †Copenhagen Wound Healing Center and *Department of Surgical Gastroenterology, Bispebjerg Hospital, University of Copenhagen, Denmark*

Aim: Alcohol abusers have increased risk of complications following s
gical procedures However, little data are avilable on the impact fr
alcohol abuse on the wound healing process
Material and methods: Sixteen patients with a daily median consu
tion of 240 g alcohol were compared with 30 elective surgical patie
(herniotomy, cholecystectomy, colorectal resections) consuming less t
60 g alcohol daily All patients had normal plasma levels of standard h
atic and renal assays Collagen and total protein accumulation in wo
granulation tissue was evaluated from the deposited amount of hydro

proline (HP) and proline (PR) in two subcutaneously implanted ePTFE tubes (Impra®, pore size: 90–120 μm). Following removal of the tubes on day 10 and hydrolysis of the deposited tissue, the content of HP and PR was determined by a high performance liquid chromatography assay and expressed as amount per length of ePTFE.

Results: PR was significantly lower in the group of alcohol abusers median 720 nmol/cm (inter-quartile range: 687–813) than in the group of surgical patients 884 nmol/cm (717–1062), *P*<0·05. HP in the group of alcohol abusers and surgical patients were 11·3 nmol/cm (4·6–15·9) and 11·1 nmol/cm (6·3–15·3), n.s., *P*=0·54.

Conclusion: The results indicate that the healing process is generally slowed in alcohol abusers as expressed by the reduced amount of total protein deposited in granulation tissue. This data may partly explain why alcohol abusers have an increased risk of wound complications. We are currently testing if 2 months of alcohol abstinence in chronic alcohol abusers reverses the depressive effect on wound healing.

Pilonidal sinus: 'jeep disease' or 'jean disease'

K. Hakan and U. Mehmet *Middle East Technical University Medical Centre, Inonü Bulvari, 06531, Ankara, Turkey*

In 1944, Dr. Louis Buie presented his classic paper in which he named pilonidal sinus as 'jeep disease'. Following this paper, it has been reported in several articles that the disease is frequently met in military personnel and that it is due to such factors as the use of jeep and other vehicles, excessive physical activity, heavy military clothes and equipment, and subsequent sweating.

Half a century later, we observed in the Middle East Technical University Medical Centre (METU-MC) that pilonidal sinus is commonly seen in students who wear jeans in their daily life. Jeans cover the legs and gluteas tightly, prevent air circulation, and cause increased sweating. Thus, we analysed our pilonidal sinus patients by questioning them about their clothing preference.

Results: Thirty-seven students with pilonidal sinus were admitted to METU-MC in an eight-month period (83·8 per cent), presented a pilonidal abscess at the first admission. 86·5 per cent of the patients answered our question about their clothing preference as they regularly or frequently wore jeans.

	Regularly (7 days/week)	Frequently (4–6 days/week)	Sometimes (1–3 days/week)	Never (0 day/week)
Jeans in daily life	27 (46·0%)	15 (40·5%)	2 (5·4%)	3 (8·1%)

Conclusions: There seem to be two important factors for developing pilonidal sinus; young age and personal hygiene. University students are already in the peak age group and if they do not care for personal hygiene, they may develop pilonidal disease.

In a population study of Minnesota college students, pilonidal sinus was noted at routine physical examination in 1·1 per cent of males and 0·11 per cent of females. We have 11 991 male students and 6459 female students in our university. It means a potential of approximately 200 pilonidal sinus patients and more than 1000 dressings. It is hard to say that wearing jeans is an independent factor for pilonidal disease. However, our observation made us think that such clothing may cause pilonidal sinus to develop, and at least can render an asymptomatic pilonidal sinus to a symptomatic one.

Bone disease after extensive gastroenterological operations: preliminary report

P. Lampe, A. Wojtyczka, M. Lesiecka, D. Kurczabińska and Z. Górka *Department of Gastrointestinal Surgery, Silesian University School of Medicine, ul. Medyków 14, PL 40-752 Katowice, Poland*

It has been shown that resective procedures within the alimentary tract such as total gastrectomy or extensive resections of the small bowel result in the development of bone disease. Mechanisms which cause the bone loss after those operations are complex and still not fully elucidated. Recent studies revealed that neither calcium, nor vitamin D substitution can prevent the development of it, thus these deficits are not responsible for postgastrectomy bone disease. Little is known about the state of bones after oesophagectomy, pancreato-duodenectomy and colectomy.

Aim: The evaluation, which of the extensive resective procedures within the alimentary tract leads in the early postoperative period to the bone loss.

Material and methods: Six patients after transhiatal oseophagectomy (OES), ten after total gastrectomy (GX), nine after pancreatoduodenectomy (PD) and five after total colectomy (TC) were examined. Thirty patients awaiting the same type of surgery constitute the control group. Twenty-four to 36 months after surgery, bone stiffness (BS) of the calcaneus was measured (Achilles,* Lunar) and bone mass defect (BMD) as compared with the control group, was calculated. All data were subjected to ANOVA, followed by a Student *t*-test or *U* Mann–Whitney test as appropriate.

Results: Bone Mass Defect (BMD) after different extensive resections within the alimentary tract expressed in percentage of the expected value in healthy individuals matched for age, sex and body mass index.

	OES		GX		PD		TC		Total	
	Before surgery	After surgery	Before surgery	After surgery	Before surgery	After surgery	Before surgery	After surgery	Before surgery	After surgery
n	6	5	10	8	9	8	5	9	30	30
BMD*	10·50 ±1·38	17·00 ±4·50	8·80 ±1·92	12·00 ±3·41	10·00 ±2·19	20·63 ±3·39	11·60 ±3·19	10·00 ±2·16	9·97 ±1·05	14·53 ±1·73
P	0·2373		0·3989		0·0114*		0·6762		0·0277*	

*Data are mean values ± SEM.

Conclusions: In the pooled group of patients after above mentioned operations the bone mass defect was greater than observed in those awaiting similar operations. However, only in patients of the pancreatoduodenectomy groups the difference was significant (*). After colectomy an insignificant improvement was observed. Long-term studies based on more objective methods should show whether colectomy in patients with inflammatory bowel diseases improves the bone state indeed.

The use of carbon dioxide laser to control cutaneous limb recurrence from malignant melanoma

M.K. Lingam, D. Byrne and A.J. McKay *Department of Surgery, Gartnavel General Hospital, Glasgow*

Surgical excision of cutaneous malignant melanoma metastases is only practical when the number of lesions is small. In lesions confined to the limbs, isolated limb perfusion (ILP) has been our treatment of choice for the past 10 years. This, however, is not possible in all patients. We present our experience with carbon dioxide laser ablation as an alternative treatment in the control of cutaneous metastases in such patients. Between September 1992 and November 1996, 29 patients (20 female and nine males) underwent a total of 57 laser treatments. The lesions were situated on the face, chest, arm and leg. The number of lesions per patient ranged from two to 43 nodules. A Sharplan 1030 portable carbon dioxide laser was used. All procedures were carried out under general anaesthesia. Each lesion was destroyed using a focused laser beam of 10–20 watts with a beam size of 0·5–1·0 mm. Twelve patients have had multiple laser treatment in the attempt to control local disease, the most being seven treatments in one patient. At a mean follow-up of 18 months, six patients have died from the disease. In the 23 patients who are alive, 18 have had no recurrence of the disease and five have had partial control of local disease. Our experience suggests that carbon dioxide laser ablation of cutaneous metastases is a minimally invasive procedure which gives effective palliation.

Lymphatic mapping to identify sentinel node in patients with malignant melanoma

M.K. Lingam, D. Byrne, R.M. MacKie and A.J. McKay
Department of Surgery, Gartnavel General Hospital, Glasgow, Scotland

Controversy still surrounds elective lymphadenectomy for treatment of patients with clinical stage I malignant melanoma. We have assessed a new technique first described by Morton *et al.* which allows identification of patients with involved lymph nodes who may benefit from elective lymphadectomy. The technique is based on the hypothesis that metastases occur along the lymphatic channels to a sentinel lymph node (the draining lymph node nearest the site of the primary malignant melanoma). Patent Blue V dye 0·5–1·0 ml is injected intradermally around the site of the melanoma. Immediately the groin or axilla is opened and the blue lymphatic channels are followed to the sentinel node. The node is removed and examined by both H&E and immunohistochemical staining. If the node is positive, radical lymphadenectomy is carried out. We have carried out this technique in 40 patients. In all patients sentinel nodes were identified, nine were found to have unsuspected micrometastases. In patients undergoing iliac perfusion, iliac lymph nodes were also sampled. The technique is practical and easy to master. It reliably identifies patients who may benefit from elective lymphadenectomy. If 25 per cent of patients with cutaneous malignant melanoma who are clinically stage I have nodal disease, this has great importance in the staging and treatment of the disease and for all therapeutic trials in the future. This technique of identifying the sentinel node and assessing lymphatic involvement has potential applications in breast and vulval carcinoma.

Do marker enzymes exist for malignant tumours?

A. Péter, E. Sárváry, K. Beck, B. Nemes, F. Alföldy, B. Sulyok and F. Perner *Semmelweis Medical University Transplantation and Surgical Clinic, 1082 Budapest, Baross u. 23, Hungary*

Introduction: The diagnostic value of serum enzymes in diagnosis of malignant tumours is controversial. The aim of our study was to investigate the characterization certain malignancies with serum enzyme levels.
Method: Serum enzyme activities of tumour patients prior surgery and healthy control group were measured kinetically. The activities of the investigated enzymes – alkaline phosphatase (ALP), dipeptidyl-peptidase-IV (DPP), leucine-aminopeptidase (LAP) and gamma-glutamyl transferase (GGT) were expressed in U/l. The colorectal, hepatic, gastric, renal and breast malignancies were verified histologically.
Results:

Cancer localisation	ALP U/l	DPP U/l	LAP U/l	GGT U/l
Colon	187·0±282·5	9·5±3·9	23·4±15·4	46·2±69·9
$n=39$	$P<0·05$	n.s.	n.s.	n.s.
Liver	733·2±526·9	22·3±8·9	106·5±47·8	198·9±153·7
$n=10$	$P<0·001$	$P<0·001$	$P<0·001$	$P<0·001$
Stomach	133·3±38·5	8·5±2·5	32·2±15·9	39·7±21·4
$n=9$	$P<0·01$	n.s.	n.s.	n.s.
Kidney	133·7±58·7	12·0±4·5	32·1±10·3	39·4±23·5
$n=7$	$P<0·01$	n.s.	n.s.	n.s.
Breast	148·3±21·2	10·6±2·9	29·1±12·9	35·1±9·6
$n=7$	$P<0·01$	n.s.	n.s.	n.s.
Control	73·6±52·3	8·6±5·6	22·2±15·0	31·7±30·0
$n=26$				

Increased enzyme values were detected in patients with hepatic cancer (HCC and cirrhosis!). ALP proved significant higher also in the other tumour groups. However, the average values are in normal range or were minimally increased. Changes of the serum enzyme activities were not significant seven days after surgery.

Conclusion: The examined enzymes are not perfect and specific diagnostic markers of malignant tumours. Further examinations with higher number and different groups of patients are necessary.

What can the endoscopist do for *Helicobacter pylori* positive children

G. Rakoczy, Z.S. Ruzsics and L. Szőnyi *First Paediatric Department of Semmelweis Medical University, 1083 Budapest, Bokay J. u 53, Hungary*

Aim: We want to draw attention to the transmission of *Helicobacter pylori* (HP) within the families.
Methods: Fifty children of HP positive parents were serologically and/or histologically investigated, and another 50 children were tested by PCR on presence of HP in their oral cavity. VacA, CagA, and UreC genes during PCR testing and Orion Diagnostics Pyloriset Latex agglutination test were used.
Results: In the first group 52 per cent of the children were serologically positive, and we found in the same group 70 per cent histologically positivity concerning the children who had upper abdominal pain. In the second group 20 per cent of the children were HP positive by PCR, and 80 per cent of the parents of these children had gastroduodenal ulcer in their history.
Conclusion: As an endoscopist when making the diagnosis of an HP infection in an adult, you should every time think of the children of those, and if there is a clinical suspicion of HP infection, the child should be clinically examined on that (supported by OTKA T-22829).

Free flap reconstruction in head and neck tumours

Z.S. Révész, M. Kásler, G. Gulyás, K. Pólus, E. Remenár, J. Hankiss, A. Boér, E. Iványi and F. Oberna *National Institute of Oncology, Budapest, H-1525, Hungary*

Free flap reconstruction surgery with microvascular anastomosis was successfully applied in 30 cases, to extended T_4 head and neck tumours. Hereby we report on our clinical observations. In our practice the free flap reconstruction technique has not prolonged survival in a significant manner. In patient's quality of life (improved nutrition, phoniatry, restoration of earlier social relations), however, profound changes have developed.

Expression of Pepsinogen C by cutaneous malignant melanomas and correlation with clinical and histological parameters

*C. Serra, †I. Quintela, ‡L.O. González, †A.M. Merino, *A. Baltasar, *J.L. Losa and †F. Vizoso **Servicio de Cirugía y Anatomía Patológica, Hospital 'Virgen de los Lirios', Alcoy 03804, Alicante, Spain †Servicio de Cirugía General y Anatomía Patológica, Hospital de Jove, Gijón, Aturias, Spain ‡Servicio de Anatomía Patológica, Hospital de Cabueñes, Gijón, Spain*

Introduction: Malignant melanoma of the skin (MMS) is a tumour with a rising incidence in the western countries. The more accepted prognostic factor of this tumour is the histologic evaluation of the depth of invasion according to criteria reported by Breslow and Clark. However, we need to find new prognostic markers in order to reach more clinical information with prognostic implications.

Material and methods: In order to evaluate the potential prognostic value of Pepsinogen C (Pep C) in malignant melanomas of the skin (MMS) we have studied a group of 35 patients with MMS and examined intratumoral Pep C expression using immunohistochemical methods.

Results: A total of 20 MMS (57 per cent) stained positively for Pep C. No significant association was found between Pep C expression and age of patients, histological type or tumoral localization. However, Pep C was significantly associated with sex of patients, predominant cytological type of tumours, and Breslow and Clark criteria. Thus, the percentage of Pep C positive tumours was higher in male patients with MMS (81 per cent) than in the females (36·8 per cent) (P=0·02); and so in epithelioid predominant tumours (77·7 per cent) than in fusocellular predominant tumours (33·3 per cent) (P=0·03). Similarly, the percentage of Pep C positive tumours was significantly higher in IV–V Clark tumours (83·3 per cent) than in I–III Clark tumours (25 per cent) (P<0·01), and in tumours with more than 1·5 mm depth of invasion (78 per cent), than those tumours with a depth of invasion of less than 1·5 mm (16 per cent) (P<0·01).

Conclusion: These data demonstrate the existence of a significant percentage of MMS that express Pep C. In addition, Pep C expression by MMS could represent an indicator of unfavourable outcome and tumoral aggressiveness.

Surgery in patients with haemophilia

J. Simo, P. Matis and L. Vrtík *I. Department of Surgery, University Hospital Mickiewiczova 13, 841 05 Bratislava, Slovakia*

Surgical therapy of the patients with haemophilia is at the present time safe method due to use of a substitute antihaemophilic factor VIII, IX and recombinant factor VII. In these cases it is necessary to use surgical procedures, which minimalized a perioperative risk of the bleeding. In a cooperation with haematologist is unavoidable a substitution of the antihaemophilic factor and to achieve its optimal level.

In the years 1989–1996 we have performed 25 operations of haemophilic patients – 18 elective and seven urgent with five haemorhagic complications, two cases were treated operative, three others were treated by conservative methods. Thirty-one patients were observed due to surgical complications of haemophilia. Mortality was 0 per cent.

Conclusions: Surgical therapy of the haemophilic patient at the present time is a safe method. It requires: 1. Urgent substitution of the antihaemophilic factor and the achievement of its optimal level; 2. Only i.v. or s.c. application of the drug; 3. Don't use anticoagulants or antithrombotic drugs. 4. In emergency use of the most conservative methods. 5. The associations of elective procedure.

Splenectomy and spleen autotransplantation due to splenic cyst

L. Tóth, K. Takáts, Z. Balika and J. Felker *Surgical Department of City Hospital, 8061 Mór, P.O. Box 31, Hungary*

Splenectomy is known to increase the risk of overwhelming postsplenectomy infection (OPSI). There is a decrease in IgM and T-lymphocytes, primary antibody response to antigen challenge is impaired, altered opsonic function and properdin an tuftsin deficiency are noted. Autotransplantation is one of the possibilities to preserve splenic functions. The authors performed spleen autotransplantations in two cases after the splenectomy of cystigerous spleens. Ten pieces from the intact spleens, each sized 10 × 20 × 2 mm (called Furka's spleen chips) were implanted in between layers of the great omentum. The function of the reimplanted splenic tissue was demonstrated by scintigrafic investigations.

Does pneumoperitoneum during laparoscopy lead to bacterial translocation

T. Tuğbay, O. Serdar and *T. Alper **Ankara University Medical School, Department of Surgery and Microbiology, 06100 Sıhhıye, Ankara, Turkey*

Aim: Although the effects of high intra-abdominal pressure on cardiac, respiratory and renal systems were evaluated in the past, there are limited numbers of studies concerning its effect on intestinal circulation. There is an uncertainty that pneumoperitoneum is leading to bacterial translocation. Our aim is to determine whether increase of intraabdominal pressure caused by carbon dioxide (CO_2) insufflation during laparoscopy leads to bacterial translocation.

Material and methods: Eighteen male dogs were used, of which seven constituted the control group (group I). Pneumoperitoneum was performed by CO_2 insufflation until intraabdominal pressure reached 15 mmHg. After 30 minutes (group II) and 120 minutes (group III) laparotomy was performed in order to investigate bacterial translocation in the samples of peritoneal smear, mesenteric lymph nodes, caecum wall, liver and spleen. Histopathological examinations were also performed.

Results: In the samples taken from the peritoneum, mesenteric lymph nodes, liver and spleen no bacterial growth was established. Bacterial colonization was significantly more in the samples taken from the caecum wall in group II (P<0·05) and group III (P<0·01) compared to the control group. Histopathological examination of the mesenteric lymph nodes showed reactive changes in group II and obvious sinus histiocytosis in group III. The changes in the mesenteric lymph nodes were the evidence of bacterial drainage.

Conclusions: More research should be conducted and emphasis should be placed on subject that intraabdominal pressure increase can cause to bacterial translocation and this could lead to multiple organ dysfunction.

Gastrointestinal stromal tumours (GIST): our surgical experience

K.P. Zeri, F.M. Di Matteo, N. Peparini, A. Maturo, D. Mascagni, A. Filippini, G. Tumino and M. Monti *III Surgical Department (Chief Prof. G. Di Matteo), 'La Sapienza' University of Rome, Viale Regina Elena, 324, 00161 Rome, Italy*

The gastrointestinal stromal tumours are relatively rare and their clinical behaviour at discovery is often unpredictable. In fact, besides the cases spread beyond the organ of origin and those with distant metastasis that have a clear malignant behaviour and a poor prognosis, the histological definition of their malignancy is not easy. Although the high mitotic count is usually considered the best prognostic factor, tumour and cell size, cellularity, nuclear and cellular pleomorphism, cellular atypia, nuclear hyperchromatism and tumoral necrosis are variously correlated to the behaviour of the tumour; some of these parameters are highly subjective and in their values there is considerable overlap between benign and malignant tumours so that it is not possible to utilize them as discriminating factors. For the definition of malignancy a multidisciplinary approach that combines clinical, routinary histological and immunohistochemical data is useful, but not all of these parameters can be promptly available for intraoperative diagnosis. This renders more difficult the choice of the most appropriate surgical approach that can range from a wedge resection to a partial or complete organ resection; often palliative surgery is the only possible solution. Being as lymphadenectomy in GIST does not effect survival, it is not indicated: lymphatic spread is not the primary route of metastasis. A long-term follow-up is mandatory due to the unpredictable behaviour of GIST. We present our cases of GIST indicating for each of them the surgical approach and the long-term outcome. Waiting to complete the follow-up, based on our experience, we think that while choosing the most appropriate surgical treatment must be considered an oncologic safety margin not only in highly malignant GIST but also in those cases with impredictable behaviour and that cannot be definitively assessed by intraoperative histology.

Urgent gastrointestinal surgery following vascular reconstructions

Gy. Acsády, L. Entz, G. Szabó and Á. Laczkó *Department of Cardiovascular Surgery of Semmelweis Medicine University, H-1122 Budapest, Városmajor u. 68*

17 119 vascular operations were carried out between 1 January 1990 – 31 December 1997 in our institute, 10 574 cases of them were reconstructive vascular surgery and 3410 interventions from them were performed due to different aorto-iliac diseases. Fifty-three urgent gastrointestinal procedures became necessary and 28 cases from them occurred either in one stage or in the same hospitalization. Vascular graft reconstruction was performed in 22 cases, but we observed graft infection only in five cases The male/female ratio was 20/8 with a mean age of 65·2 years (41–87).

The aetiological findings were as follows: a) visceral embolism in two cases; b) atherasclerotic occlusion in nine cases; c) abdominal aortic aneurysm in nine cases; d) aorto-enteric fistula in four cases; e) haemorrhage of gastric ulcer in one case; f) cancer of the stomach in one case, g) intraoperative intestinal damage in two cases.

The mortality of these operations was 35·7 per cent (10/28). The causes of the high incidence of fatal outcome were either diffuse peritonitis or cardiorespiratory insufficiency.

Conclusions: It is rarely necessary to combine the aorto-iliac reconstructive surgery with urgent gastrointestinal operations, but the mortality rate is very high in these cases This can be reason of the rare occurrence of graft infection too

Intra-operative complications during endoluminal exclusion of infra-renal aortic aneurysms

M. Argnani, V. Stancanelli, E. Piccinini, R. Altini and G.U. Turicchia *Vascular Surgery Unit, Surgical Department, S. Maria delle Croci Hospital, Ravenna, Italy*

The authors briefly present some cases with important technical problems occurred during the positioning of endoprothesis for endoluminal exclusion of infra-renal aortic aneurysms In these some patients a graft displacement occurred both proximally and distally and a re-positioning has been mandatory as well as a lengthening of one or both iliac branches in other cases. The complications have been managed with a technical cunning during the same operative session thus avoiding a conversion into an open technique, and leading to the success of the treatment

Carotid endarterectomy without angiography?

Á. Baranyai, B. Dlustus, Gy Tóth, G Vallus, L. Tóth, *L. Szentpétery and †T. Kerényi *Department of Vascular Surgery, †Pathology, Central Military Hospital, Budapest H-1134 Róbert krt. 44. *Department of Diagnostic and Interventional Radiology, BM Central Hospital, Hungary*

Carotid duplex is a highly sensitive and accurate screening test, but catheter arteriography is the definitive preoperative study for carotid artery stenosis. However, its associated risks and cost have prompted the development of other imaging techniques Authors investigate if carotid endarterectomy can be done without angiography on the basis of non-invasive imaging techniques alone. Preoperative findings of duplex, CT, TCD examinations and angiography of 100 randomized patients who underwent carotid eversion endarterectomy between 1996 and 1997, have been analysed retrospectively Sensitivity, specificity, positive and negative predictive value and accuracy of the duplex vs angiography at stenosis of different grade (1–66 per cent, 67–90 per cent, 91–99 per cent, 100 per cent) have been calculated Diagnostic pitfalls and their consequences are discussed. Results show that the accuracy of duplex improves with increase of the grade of the suspected hemodynamic stenosis. Sensitivity and specificity reach 100 per cent and 97·9 per cent at the stenosis of grade 91–99 per cent. In the majority of the diagnostic pitfalls, ultrasound overestimated the grade of stenosis vs angiography. Therefore, there is a need on preoperative angiography in the case of significant, but non-critical stenoses At critical hemodynamic stenoses (91–99 per cent) it should be considered to give up angiography.

Durability of renal revascularization for preservation of renal function

A Brannigan, J. Donohoe, M.K. O'Donohoe and T.P. Corrigan
Mater Misericordiae Hospital, Dublin 7, Ireland

Renal artery stenosis resulting in a reduction in renal function is a major cause of chronic renal failure requiring haemodialysis. Surgery to preserve renal function in these patients can give excellent results.

The results of surgery for renal artery stenosis in 17 patients with 22 renal artery stenoses or occlusions and deteriorating renal function are reviewed The mean age was 60 years and male female ratio 8.9 Four patients were dialysis dependent and six had combined aortic and renal disease. Surgical procedures performed included aorto-renal, and iliorenal bypasses with combined aortic replacement with tube, aorto-iliac or aorto-femoral bypasses in six patients. Autogenous saphenous vein was used in 12 patients.

The mean follow-up is 60 months (range 12–120) There was no peri-operative mortality. Mean arterial blood pressure fell from a preoperative level of 191/107 mmHg, on therapy, to a current level of 142/81 mmHg ($P<0·001$). Mean serum creatinine fell from 445 µmol/l preoperatively to 250 µmol/l currently ($P<0·02$). Two dialysis dependent patients required no further dialysis following surgery Medication fell in both dosage and number of agents from a mean of 2·3 agents pre-op to a current level of 1·6 ($P<0·05$) Renal function was maintained or improved for the duration of follow-up in all but two patients. Nine patients are still alive. One patient required further dialysis five years following surgery and renal function deteriorated two years post surgery in one patient.

It is concluded that renal artery surgery for preservation of renal function is a worthwhile procedure in patients with renal artery stenosis and deteriorating renal function

Iliac Wallstents and endovascular repair of abdominal aortic aneurysms (AAA): a useful combination?

A.S. Brown, J. Rose and M.G. Wyatt *The Northern Vascular Centre, Level 4, Freeman Hospital, Newcastle upon Tyne, England*

Aims: Iliac arterial tortuosity and luminal narrowing can cause problems during insertion of bifurcated aortic stent grafts with possible limb occlusion We aimed to review the effect of prophylactic iliac stenting on the outcome of AAA stent grafts and associated radiological exposure.

Methods: During a 22 month period, 40 patients underwent endovascular treatment of infra-renal AAAs. In all cases a bifurcated device was successfully deployed Nine patients were noted to have an iliac stenosis or narrowing with significant tortuosity Wallstents were placed in the iliac vessels of all nine patients (seven unilateral, two bilateral) prior to insertion of the aortic stent Follow-up was by CT scan at 1, 3, 6, 12, 18 months (median six; range 1–21 months)

Results:

	Wallstent	No Wallstent	*P*
Number	9	27	
Median fluoroscopy time	27 mins	32 mins	n s
Median contrast volume used	350 mls	290 mls	n s

Two early and two late iliac limb occlusions have occurred, none on the group pre-treated with Wallstents. One early occlusion occurred during treatment of a proximal endoleak. The remaining three have all been associated with significant iliac angulation (>80°) There were no procedural deaths or conversion to open repair. One patient pre-treated with a Wallstent died on day six from a myocardial infarct. Of the remaining eight patients, all have patent iliacs bilaterally, no endoleaks and no distal complications. Overall 30 day mortality = 5 per cent (11·1 per cent for the Wallstent group).

Conclusion: A high proportion of bifurcated stent grafts will occlude at least one limb in the presence of iliac tortuosity or stenosis. Wallstents appear to decrease this occlusion rate without significantly increasing radiological time, allowing easier stent graft deployment.

Direct analysis of free radical release during aortic aneurysm repair by electron resonance

A.S. Brown and M.G. Wyatt *The Northern Vascular Centre, Level 4, Freeman Hospital, Newcastle upon Tyne, England*

Aims: Reactive free radical species (ROS) generated during abdominal aortic aneurysm (AAA) surgery have been implicated in the resulting ischaemia–reperfusion injury. Our aim was to determine the applicability of Electron Spin Resonance (ESR) spectroscopy for analysis of ROS produced during AAA repair.

Methods: Using a femoral line, 1 ml blood samples were obtained from six patients undergoing open AAA repair. These were immediately mixed with 0·5 ml of α-phenyl-N-tert-butyl nitrone (PBN, 50 mM in 0·15 M NaCl) spin trapping agent, and the mixture frozen in liquid nitrogen. After thawing, vortex mixing with 0·5 ml toluene and centrifuging at 10 000 g, the clear supernatant was flame sealed in a glass capillary tube for analysis via ESR spectroscopy. The height of the central peak of the triplet PBN-adduct spectrum is proportional to the ROS content of the sample allowing comparison.

Results:

Sample		Free radical content (arbitrary units) [mean ± SD]	
Pre-clamping		230±100·14	
Post-clamping:	10 min	506±170	$P<0\cdot03$
	1 hour	229±84·87	$P>0\cdot4$ (ns)
	4 hours	419·111·05	$P<0\cdot04$
	24 hours	534±177·9	$P<0\cdot05$

Conclusion: This technique identifies two significant peaks in the free radical content of venous effluent from tissues undergoing ischaemic–reperfusion during open AAA repair. With refinement it could help in the development of methods to modulate the associated injury.

Change in aneurysm diameter following aortic stenting: is it a measure of success?

A.S. Brown, J. Rose and M.G. Wyatt *The Northern Vascular Centre, Level 4, Freeman Hospital, Newcastle upon Tyne, England*

Aims: If abdominal aortic aneurysms (AAA) fail to decrease, or actually increase in size following stenting, there may still be a risk of rupture. Our aim was to examine early changes in AAA size following apparently successful aortic stenting.

Methods: Forty AAAs have been repaired using a bifurcate system. The maximum aortic diameter was recorded for each patient on a preoperative CT scan. Follow-up scans have been performed at regular postoperative intervals (0, 1, 3, 6, 12 + 18 months). All scans have been examined for endoleak and change in AAA diameter by a consultant interventional radiologist. Patients have been grouped dependant upon intitial AAA size (Group 1: 45–54 mm; Group 2: 55–64 mm; Group 3: >65 mm).

Results: Two patients died prior to discharge. Thirty-three patients have reached one month follow-up (median six months; range 1–21 months). Changes in AAA diameter are shown as percentage of the immediate postoperative measurement (giving median values and ranges).

	Group 1	Group 2	Group 3
Number of patients	11	14	8
Median FU (months)	6	6	6
% diameter change	–4·3 (–28·8 to +1·5)	–2·4 (–30 to +8·3)	–2·4 (–15·6 to +4)

Since stent insertion 20 aneurysms have decreased, seven increased and six remained unchanged in size. Two patients have increased by greater than 5 per cent and neither have an endoleak evident on CT.

Conclusion: Despite an apparently successful procedure CT scanning has revealed shrinkage of the sac in only 60·6 per cent of patients and AAA diameter has actually increased in 21·2 per cent. These patients may have small endoleaks undetected on CT and interpretation of 'stenting success' should be guarded until long-term results are available.

Postural effect on lower limb arterial calf inflow in health and peripheral vascular disease

K. Delis, N. Labropoulos, A. Nicolaides, V. Ibegbuna, A. Lennox, B. Glenvile and G. Stansby *Academic Vascular Unit, Imperial College School of Medicine, St. Mary's Hospital, London, UK*

Aims: To comparatively evaluate the effect of postural alteration on lower limb arterial flow velocity haemodynamics a) in healthy subjects and b) in patients with intermittent claudication (IC) (Fontaine II) due to peripheral vascular disease (PVD).

Material and methods: The postural effect was evaluated in 37 limbs of healthy subjects (Group 1) and 50 limbs of patients with IC (Group 2, ABI range 0·39–0·76; median 0·57) using duplex U/S (HP Sonos 2500). All patients in group 2 had superficial femoral artery (SFA) disease. Flow haemodynamics (mean and SD) [volume flow (Q) (ml/min), mean velocity (MV), peak systolic (PSV), end diastolic (EDV) velocities (cm/s) and pulsatility index (PI)] were measured in the lying (L) and sitting (S) positions.

Results:

Group 1	MV	PSV	EDV	PI	Q
Lying	8·8 (12–5)*	54 (66–41)*†	4·7 (6–4)*	6 (8–4)†	111 (154–68)*
Sitting	4·5 (6–3)	37 (46–28)†	3·4 (4–3)	9 (11–6)*†	57 (83–30)
Group 2					
Lying	12·5 (17–8)*†	29 (42–16)*	5·8 (8–4)*	2 (3–1)	113 (166–61)*
Sitting	8·4 (12–5)†	23 (33–13)	4 (6–3)†	2·5 (4–1)*	76 (116–35)†

*: $P<0\cdot01$ Intragroup (L vs S) (Wilcoxon SR).
†: $P<0\cdot01$ Intergroup (L vs L) (S vs S) (Mann Whitney).

Conclusions: Lower limb arterial Q and flow velocities decrease significantly when posture is altered from lying to sitting both in normal subjects and claudicants. This and increase of PI on sitting indicate enhancement of arterial resistance to flow secondary to peripheral vasoconstriction. The orthostatic response in claudicants is significantly attenuated reflecting a marked derangement in the quality of the veno-arteriolar reflex. Understanding these postural changes is a key to the development of therapeutic measures to improve flow and collateral circulation. Mechanical means, such as impulse devices, by reducing peripheral resistance to flow on sitting, have shown promising results in the treatment of intermittent claudication.

Duration of arterial calf inflow enhancement with Intermittent Pneumatic Compression of the calf

K. Delis, V. Ibegbuna, A. Lennox, N. Labropoulos and A. Nicolaides *Academic Vascular Unit, Imperial College School of Medicine, St. Mary's Hospital, London, UK*

Recent data indicate that Intermittent Pneumatic Compression (IPC) applied daily (2–3 hours) can significantly improve the haemodynamics and walking ability of patients with Intermittent Claudication (IC) due to PVD. Delivery of a pneumatic impulse to the leg expels the venous blood

up to the thigh and enhances shear stress in the vessel walls, causing increase of the arteriovenous gradient and release of endothelium dependent relaxing factors that attenuate peripheral resistance and increase arterial flow.
Aim: To determine the flow velocity changes that occur in the arterial calf inflow when the leg is subjected to a pneumatic impulse in healthy subjects and patients with IC.
Material and methods: Twenty-four normal limbs (N) and 26 limbs with PVD (IC) matched for age, sex and risk factors. All PVD legs examined had a patent popliteal artery and a severely diseased superficial femoral artery. Arterial calf inflow haemodynamics [volume flow (Q ml/min), the mean (MV), peak systolic (PSV) and end diastolic (EDV) velocities (cm/s), and pulsatility index (PI)] were obtained in the popliteal artery using Duplex U/S after a 20 minute rest. Measurements were obtained at rest and during the application of IPC in the calf, through to 50 seconds after the delivery of the impulse (140 mmHg, 4 sec). Data were analysed at rest (0) and 5, 15, 25, 35, 45 and 50 sec from the cessation of impulse.
Results:

		0s	5s	15s	25s	35s	45s	50s
Q	N	49	179*	120*	88*	60*	49	49
	IC	55	163*	92*	77*	71*	65*	64*
MV	N	4†	15*†	10*†	8*†	5*†	4†	4†
	IC	8·4	21*	15*	2·5*	11*	9·4*	9*
PSV	N	39·2†	56*†	46*†	44·5*†	41·6*†	39·2†	39·15†
	IC	22·1	41·9*	32·8*	30·5*	28·1*	24·3	24·3
EDV	N	3·4	9·2*	5·6*	4·1*	3·7	3·4	3·4
	IC	3·8	11·7*	7·2*	5·2*	4·1*	3·9	4·28
PI	N	9·3†	3*†	4·5*†	4·9*†	7·1†	8·8†	9·3†
	IC	2·3	1·47*	1·73*	2·02*	2·36*	2·27	2·35

*: $P<0·01$ intragroup comparison (Wilcoxon ST).
†: $P<0·01$ intergroup comparison (Mann–Whitney).

Conclusions: Arterial calf inflow velocity augmentation achieved on application of IPC is a phenomenon lasting up to 35 seconds in healthy subjects and more than 50 seconds in patients with IC due to PVD. Three phases can be demonstrated, an early one characterized by maximal levels of flow velocities and minimal PI, a middle phase where flow velocities are markedly attenuated, and a final one representing an asymptotic slow return to baseline. Flow enhancement with IPC is associated with a significant increase of EDV and attenuation of PI, indicating that the involved mechanisms act by reducing peripheral resistance to arterial flow.

The surgical treatment of the extremity vascular injuries

B. Dlustus, Gy. Tóth, Á. Baranyai and G. Vallus *Department of Vascular Surgery, Central Military Hospital, Budapest H-1134, Róbert Károly krt. 44, Hungary*

The frequency of the vascular trauma in the civilian life has increased significantly in the past decade in Hungary. This is due to more automobile and industrial accidents, the appalling increase in gunshot and stab wounds and the increasing use of therapeutic and diagnostic techniques involving the cannulation of major blood vessels. The consequences of the vascular trauma – like haemorrhage and ischaemia – threaten the patient's life.

During the period 1986–1997, 81 civilians with 100 vascular injuries were treated. Eighty-five primary repairs and 15 late operations for traumatic false aneurysms and arteriovenous fistulas were performed. Penetrating trauma occurred in 55, gunshot in 13 and blunt in 18 of patients. Fourteen indirect injuries like hyperextension, deceleration and arteriospasm were encountered. Nearly 80 per cent of injuries were located on the extremities; 35 isolated vascular and 46 multiple traumas were treated. Concomittant bone in 20, peripheral nerve in 18, cerebral in seven and abdominal or thoracic organ injuries were observed in 10 patients. Stable patients underwent complete vascular evaluation including arteriography. The haemodynamically unstable patients were brought directly to the operating room. Preoperative arteriography was needed in 20 of 90 arterial injuries. Vascular injuries were amenable to repair by means of lateral suture or using autologous vein or PTFE grafts.

The correct diagnosis of the vascular trauma, the minimalized duration of ischaemia by appropriate cooperation in planning repair procedures between orthopaedics and vascular surgeons are the most important factors of the surgical treatment.

Renal artery stenosis: the significance of its incidental finding on peripheral angiography

P.D.F. Dodd, J.B. Fitzgerald, M. Bukhari, M.S. Baguneid, G.D. Griffiths, N. Chalmers and M.G. Walker *Department of Vascular Surgery, Manchester Royal Infirmary, UK*

Aims: As more angiograms are being performed for lower limb ischaemia RAS is increasingly diagnosed as an incidental finding. We aimed to determine the prevalence of RAS in patients with peripheral vascular disease and its impact on patient outcome.
Methods: All peripheral angiograms performed over a two year period were independently reviewed to determine the degree of RAS. Those patients found to have RAS of 50 per cent or more were then studied further. Mortality risk factors were recorded and statistical analysis performed using χ^2-squared tables with Yates' correction. Follow-up was available for a minimum of two years and a maximum of four years.
Results: Analysis of 1102 consecutive angiograms revealed 156 (14·2 per cent) patients with RAS. In this group there was a high overall mortality rate of 21·2 per cent, hypertension and diabetes were common, 62·7 per cent and 20·6 per cent respectively, whilst elevated serum creatinine >130 µmol/l was found in 10·9 per cent. Bilateral or severe unilateral stenosis >90 per cent was identified in 43·6 per cent. However, the only risk factor useful in identifying a high mortality sub-group was elevated baseline creatinine (P=0·004, two-tailed t-test).
Conclusion: We conclude that the prevalence of RAS merits flush aortography to visualize the renal arteries in all patients undergoing peripheral angiography. Furthermore, any patient with pre-existing elevation of creatinine and RAS is at exceptionally high-risk and merits urgent investigation of renal and cardiac function.

Non-invasive evaluation of the effect of posture on lower limb arterial blood flow in patients with claudication

H. Elmorsy, K. Dalies, T. Elatrozy, S.A. Jmor, M. Griffin and A. Nicolaides *St. Mary's Hospital, QEQM Wing, Academic Vascular Surgery, London, UK*

Aims: To determine the influence of posture on the arterial blood flow in the lower limbs in patients with and without peripheral arterial vascular disease.
Material and methods: A consecutive series of 22 patients (31 limbs) with chronic intermittent claudication short of rest pain were studied. Patients were scanned using 5·5–7·5 MHz high resolution line scan head probe. The popliteal artery blood flow and pulsatility index were calculated from the Doppler spectral waveform. These measurements were taken in horizontal as well as in sitting position. Eight normal individuals with matched age and sex (16 limbs) were recruited and the same measurements were repeated (control group).
Results: In the control group the mean popliteal blood flow in the horizontal position (102·9±41·5) ml/min was significantly higher (P=0·0039) than in the sitting position (62·5±38·7) ml/min. However, in claudicant group the mean popliteal blood flow in the horizontal position (96·1±57·3) ml/min was not significantly higher (P=0·0809) than in the sitting position (69·9±45·8) ml/min. The change in posture has produced a significant change (P=0·0226) in the pulsatility index in the control group from the sitting position (10·50±7·88) to the horizontal position (4·97±3·79). However, the change in posture has produced a non significant change (P=0·8470) in the pulsatility index in the claudicant group from the sitting position (2·919±2·40) to the horizontal position (3·070±2·97).
Conclusion: The results indicate that posture plays an important role in the haemodynamic arterial blood flow changes. This might have an implication in rehabilitation of patients with chronic leg ischaemia.

High resolution ultrasound prior to endarterectomy: the accuracy of grading ICA stenosis

S.A. Jmor, T.I.S. Elatrozy, H. Elmorsy, M. Griffin and A.N.N. Nicolaides *Irvine Laboratory for Cardiovascular Investigation and Research, Imperial College School of Medicine at St. Mary's, QEQM Wing, London, UK*

Aim: The aim of this study was to evaluate the accuracy of ultrasonic B-mode images of ICA in estimating the degree of stenosis.

Material and methods: In a random consecutive series of patients scheduled for CEA routine duplex scanning was performed using ATL HDI 3000 and 7–4 MHz probe. Good quality images in B-mode (both in longitudinal and transverse views) were frozen on the screen. The percentage diameter and area reduction were calculated from each view respectively. Peak systolic (PSV) and end diastolic velocities (EDV) were measured at the proximal CCA and ICA within the jet of turbulence. The following velocity ratios were used to calculate the degree of haemodynamic stenosis (PSVic/PSVcc). (EDVic/EDVcc) and (PSVic/EDVcc). Endarterectomy specimens of the same patients were scanned immediately in a mixture of saline and gel media. The site of maximal stenosis was marked and 0·2 mm transverse pathological blocks were obtained. The duplex measurements were compared to the percentage area and diameter reduction from transverse sections of the specimens. A millimetre scale was placed next to the specimens which was captured by video. The area reduction was measured by playing the video and using the same duplex setting as above.

Results: The following table summarizes the difference in the estimated diameter stenosis using different methods in relation to that estimated from endarterectomy transverse blocks (as a gold standard). Twenty-nine out of 32 were in the region of 70–99 per cent.

Duplex method used	Percentage of cases with concordant stenosis to that estimated from the surgical specimens	Percentage of cases with disconcordant stenosis relative to that estimated from the surgical specimens
B-mode images	93%	6%
PSVica	79%	21%
EDVica	24%	76%
PSVica/PSVcca	76%	24%
EDVica/EDVcca	60%	40%
PSVica/EDVcca	76%	24%

Conclusion: The results indicate that images obtained with B-mode are the most accurate in determining the degree of stenosis. Diameter and area reduction (measured on duplex) might be more appropriate parameters to be used in studies that evaluate the sensitivity and specificity of ultrasound with angiography as gold standard.

Graft dilatation following abdominal aortic aneurysm resection and grafting

A.F. Lennox, R. Englund, D.A. Robinson and K.C. Hanel
Vascular Surgery Department, St. George Hospital, Sydney, Australia

Dilatation of aortic prosthesis following abdominal aneurysm surgery has been documented with both knitted and woven dacron grafts.

Aim: To review the experience in a single institution with both types of grafts, and to evaluate both rate and degree of dilatation, and association of dilatation with graft-related complications.

Material and methods: Between January 1987 and December 1992, elective repair of abdominal aortic aneurysm was undertaken in 219 patients. Of these patients, 146 had at least one follow-up ultrasound scan to evaluate their graft. These patients were analysed with respect to age, sex, size of initial aneurysm, type of graft, size of graft used, time of follow-up and diameter of graft at follow-up scan. Any complications referable to the graft or recurrent disease was also documented at this time.

Results: A total of 216 scans were available for analysis. There were 123 male patients and 23 female patients in the group. The mean age was 72 years, and the mean preoperative aneurysm size was 5·8 cm. Thirty-four patients had a woven dacron graft inserted, while 112 were grafted with a knitted dacron prosthesis. Mean percentage increase in size for woven dacron was 17·3 per cent, while that for knitted dacron was 38·9 per cent ($P<0{\cdot}0001$). Further analysis of the scans showed that the majority of dilatation occurred early, and the grafts were then relatively stable. No specific complications related to graft or anastamotic dilatation were noted.

Conclusions: Dilatation following implantation is a well known phenomenon affecting dacron, particularly in a knitted configuration. Some authors have suggested that graft dilatation is either an inherent failure mode of the material, or a precursor of more significant complications. This study contradicts this view, and dilatation was not associated with any adverse outcome. However, graft complications are known to be related to the weight of graft inserted, particularly in knitted grafts, and there is some question as to the dimensional stability in vivo of ultralightweight grafts. This raises concerns as to the behaviour of grafts inserted during endoluminal repairs and the possibility of late dilatation.

Duplex detected stenoses in angiographically normal vein grafts: is angiography still the gold standard?

*D.R. Lewis, *C. McGrath, *C.D. Irvine, †A. Jones, †P. Murphy, *F.C.T. Smith, *R.N. Baird and *P.M. Lamont **Department of Surgery, †Department of Radiology, Bristol Royal Infirmary, Bristol, UK*

Aim: To review the sensitivity of duplex scanning and angiography at detecting vein graft stenoses in patients on a graft surveillance programme.

Patients and methods: Since February 1993, 143 patients with 148 vein grafts (70 per cent in situ, 30 per cent reversed) have been included in a prospective, open, non-randomized study, attending postoperative infrainguinal vein graft surveillance for a minimum of six weeks, 57 graft stenoses in 57 grafts were identified by duplex scanning as a localized high velocity jet. Angiography was performed in all except 12 patients.

Results: Angiography confirmed vein graft stenoses in all but 10 patients. Of these, five patients remain stable and asymptomatic with a persisting duplex abnormality. The remaining five patients, although asymptomatic, exhibited disease progression on duplex and surgical intervention confirmed significant stenoses which were successfully treated.

Conclusion: The results suggest that duplex scanning is a reliable imaging modality for detecting vein graft stenoses. Selection for surgical correction can be made, in some circumstances on the basis of clinical and ultrasound criteria alone.

Management of patients with failed endovascular stents?

M.K. Lingam, J. Moss, P.N. Rogers, A.J. Mckay and R.O. Quin
Department of Surgery, Gartnavel General Hospital, Glasgow, Scotland

Percutaneous transluminal angioplasty (PTA) with endovascular stenting is now commonly used in the treatment of aortoiliac occlusive disease. There is limited data on the long-term outcome of patients in whom stenting fails. We have carried out a retrospective analysis of all patients who underwent stenting whom the treatment failed. Between July 1993 and July 1996, a total of 80 patients had iliac stents inserted. In 19 patients the stenting failed. There were 14 females and five males with a mean age of 55 years (range 35–92). Fifteen presented with intermittent claudication and four with rest pain. All patients had aortoiliac occlusive disease which was demonstrated on arteriography to be suitable for PTA. Six patients had Palmaz 294 stents, seven patients had kissing Palmaz 394 stents and six had wall stents. In eight patients the stents blocked immediately, but radiological salvage was possible only in four with good symptomatic outcome. In the other four patients, arterial reconstructive surgery was performed. Only one patient had a successful outcome and three patients eventually came to amputation of the lower limb. In 11 patients the stents blocked between one month and four years. In two patients radiological salvage was attempted but failed and arterial bypass surgery was performed which was successful in one patient. Of the remaining nine patients who underwent arterial reconstructive surgery, six remain symptom free and three still have claudication. Though stenting of iliac disease is widespread, our experience suggests that complications are not uncommon. Surgery, rather than further radiological intervention is usually needed.

Coexisting abdominal aortic aneurysm and intra-abdominal malignancy: which lesion to treat first?

H.L. Morris and A.F. da Silva *Wrexham Māelor Hospital, Wrexham, UK*

Background: The management of simultaneously occurring abdominal aortic aneurysm and intra-abdominal malignancy is controversial. It is unclear whether to resect the aneurysm first or the malignancy or both simultaneously. If the malignancy is resected first there is a risk of post-operative rupture of the aneurysm. If a simultaneous resection is performed there is a risk of prosthetic graft infection from contamination by gastrointestinal or urinary tract contents.

Method: All relevant papers derived from medline and manual searching were reviewed and analysed.

Results and conclusions: The literature supports the conclusion that the lesion of greatest priority is that posing the greatest threat to the patient, and that this is usually the aneurysm, especially if over 6 cm in size. For renal malignancies simultaneous resection is the treatment of choice, but for bladder cancer the best management is unclear. Aneurysms should usually be resected in preference to colorectal cancer unless the cancer is perforated or obstructed. If both lesions are complicated there is a case for simultaneous resection.

Femoro-femoral bypass

J.G. Mosley and G. Riding *Leigh Infirmary, The Avenue, Leigh, Lancashire, UK*

Aim: This is a prospective study of 75 patients who had a femoro-femoral crossover graft. The study was designed to ascertain the value and limitation of this extra-anatomical graft.

Material and methods: Seventy-five patients had this bypass for disabling claudication (24), rest pain (24) or gangrene (27) at one unit between November 1986 and October 1995. In all patients an 8 mm Dacron graft was placed behind rectus abdominus muscle. All patients had pre- and postoperative Doppler pressure studies and peroperative pressure measurements. All patients have been followed up for a minimum of two years. Data have been analysed by Student's t-test and significance assessed as $P<0{\cdot}05$.

Results: There were three deaths in the first 30 days and 17 further deaths between six months and five years. The graft significantly increased Doppler ankle pressure.

	Brachial	Ankle
Preoperative	158	57
Postoperative	139	103 * $P<0{\cdot}05$

The patency was 80 per cent at 12 months and 68 per cent at 5 years. Eight patients developed severe ischaemia or stealing of the donor limb. This was due to (1) intimal hyperplasia, (2) existing occlusion of donor superficial femoral artery, (3) the development of stenosis of the donor iliac artery.

Conclusion: A femoro-femoral crossover graft is a successful graft with good long term patency. However, a steal phenomena may occur on the donor side and those at particular risk can now be recognized preoperatively and precautions taken.

Objective mobility assessment in peripheral vascular disease and treatment by angioplasty

S.P.K. Payne and N.A.G. Jones *Northern Vascular Centre, Freeman Hospital, Newcastle-upon-Tyne, UK*

Aim: To objectively measure activity differences in the home environment between patients with peripheral vascular disease (PVD) and controls, and demonstrate whether treatment by percutaneous transluminal angioplasty (PTA) improves mobility.

Methods: Twenty claudicants and 13 controls without PVD were studied. Using NUMACT (a modified Psion$^{\mathrm{TM}}$ with two position sensors and accelerometer) postural changes (standing, sitting, lying) and activity (number and amplitude of steps) were recorded in real time for 24-hour periods. Energy was calculated as step number × amplitude (arbitrary units). Ischaemia was measured using ankle brachial pressure index (ABPI). Twelve claudiants underwent PTA and the measurements repeated two weeks later.

Results: Median standing/walking time was 186 minutes in claudicants compared with 371 minutes in controls ($P<0{\cdot}01$). Median number of steps taken was 7088 in claudicants compared with 14 216 in controls ($P<0{\cdot}01$). Median energy expenditure was 172 761 in claudicants compared with 472 505 in controls ($P<0{\cdot}01$).

In eight cases ABPI improved by $\geq 0{\cdot}15$ after PTA, in four by $<0{\cdot}15$. Cases demonstrating haemodynamic improvement showed increased standing time of 99 minutes (median) $P=0{\cdot}02$, increased number of steps by 3517 (median) $P=0{\cdot}02$ and increased energy expenditure of 135 731 (median) $P=0{\cdot}04$.

Conclusion: These data demonstrate impaired mobility in claudicants, which is improved by haemodynamically successful PTA. This has not been objectively measured before.

Selective shunting using transcranial Doppler, near infrared spectroscopy and stump pressure measurements during carotid endarterectomy

P. Robless, T. Tegos, S. Byrd, I. Williams, N. Cheshire, A. Nicolaides, A. Mansfield and G. Stansby *Academic Surgical Unit, ICSM at St. Mary's, London, UK*

Aims: Near infrared spectroscopy (NIRS) and transcranial Doppler (TCD) monitoring can be used during carotid endarterectomy (CEA) to monitor cerebral perfusion. This study aims to compare the usefulness of NIRS, TCD and carotid stump pressure measurements in selective shunting during CEA.

Method: Thirty-five patients undergoing CEA under general anaesthetic had ipsilateral cerebral oximetry and TCD monitoring of the middle cerebral artery (MCA). After carotid clamping, the mean carotid stump pressure, the fall in MCA velocity and cerebral oxygen saturation were measured.

Results: Patients were divided into those with a stump pressure >50 mmHg (18) or ≤50 mmHg (12). The median fall in MCA velocity when the stump pressure was >50 mmHg was 31 per cent compared to 51 per cent when the stump pressure was ≤50 mmHg. There was a significantly larger fall in MCA velocity when stump pressure was ≤50 mmHg ($P=0{\cdot}01$, Mann–Whitney U). The fall in MCA velocity inversely correlated with the ratio of stump pressure to mean arterial pressure (Spearman $r=0{\cdot}73$ 95 per cent CI: 0·87 to 0·48, $P<0{\cdot}0001$).

The fall in cerebral oxygen saturation was not associated with mean stump pressure ($P=0{\cdot}2$). The fall in oxygen saturation was inversely correlated with the ratio of stump pressure to mean arterial pressure (Spearman $r=0{\cdot}55$ 95 per cent CI: 0·83 to 0·06, $P=0{\cdot}03$). There were no postoperative neurological events in the study.

Conclusions: The measurement of MCA velocity by TCD may be a useful adjunct to stump pressure measurement in deciding when to use a shunt as well as for shunt monitoring. Cerebral oxygen saturation may not be as comparable, casting doubt on its usefulness in clinical practice.

Assessment of fistulography for surgery of angioaccess for haemodialysis

M. Szkilladz, P. Maciejczak and W. Stryga *St. Anna, District, Traumatology Hospital, 16/20 Barska St., 01-315 Warsaw, Poland*

The aim of this study was to evaluate the reliability of fistulogaphy of arterio-venous fistula for chronic haemodialysis.

Material and methods: Contrast medium was injected via needle inserted in arterial part of the fistula. The image intensifier was centred on the fistula and the draining veins as far as the subclavian vein subsequently. Total of 67 procedures was performed on 48 patients presenting with native a-v fistulas for haemodialysis on the upper extremities.

Results: Fistulography demonstrated following abnormalities: venous stricture 13 cases; venous aneurysm five cases; multiple venous collaterals two cases; central venous occlusion three cases. No complications related to injection, contrast dose were noted. Performed procedures resulted in 17 cases of surgery and five percutaneous transluminal angioplasty including two vascular stenting.

Conclusions: 1. Fistulography a-v shunt is a simple, safe and easy procedure. 2. Fistulography proved to be of excellent use in constructive and reconstructive surgeries of fistula and prevent early complications caused by inadequate vein draining.

Clinical correlates of embolic events on transcranial Doppler

T.J. Tegos, M. Sabetai, G. Ramaswami and A.N. Nicolaides *Irvine Laboratory, Department of Vascular Surgery, St. Mary's Hospital, 120 Praed Street, London, UK*

Aim: It was to establish the relationship between the ipsilateral embolic count (EC) in the middle cerebral artery (MCA) on transcranial Doppler (TCD), carotid plaque echodensity, ipsilateral cerebrovascular symptoms (CVS) and ipsilateral cerebral CT infarctions (CCTI).

Methods: Fifty-nine patients with 80 carotid plaques; 26 symptomatic and 54 asymptomatic, having stenosis on Duplex from 50–99 per cent were studied. The ultrasonic images of carotid plaques were normalized in a computer using two echoic reference points: the GSM (grey scale median) of the blood and the GSM of adventitia. GSM represents the median of the frequency distribution of tones in selected areas of the image. Normalization is a linear scaling (0–255 grey tones) which transforms all images so that the GSM of the blood to become 0–5 and the GSM of the adventitia to become 180–200. The GSM of the normalized image of the plaques was used as a measure of plaque echodensity. The ipsilateral MCAs were monitored on TCD for 30 minutes for the EC and the presence of ipsilateral CVS and ipsilateral CCTI were noted. Haemodynamic and lacunar infarctions were excluded since these do not have an embolic basis.

Results: The prevalence of embologenic plaques (EC>2) was higher in the echolucent (GSM<30) than in the echogenic (GSM>30) plaque population [48 per cent (20/42) – 26 per cent (10/38)] symptomatic than asymptomatic plaque population [54 per cent (14/26) – 30 per cent (16/54)] and CT infarction than CT infarction free plaque population [64 per cent (9/14) – 32 per cent (21/66)] (χ^2, $P<0{\cdot}05$).

Conclusion: These results establish the relationship between the EC, GSM, CCTI and CVS, indicating that EC can be used to identify unstable carotid plaques and suggesting their possible application in natural history studies of carotid plaques.

The progressive inflammation of peripheral vascular disease: a cause for concern?

E.P.L. Turton, J.I. Spark, K.G. Mercer, D.C. Berridge, P.J. Kent, R.C. Kester and D.J.A. Scott *Department of Vascular and Endovascular Surgery, St. James's University Hospital, Beckett St, Leeds, UK*

Introduction: Patients with PVD (Peripheral Vascular Disease) are advised to walk to their maximum claudication pain to help improve walking distance. However, each episode of claudication pain is associated with a short-lived ischaemic episode followed by one of reperfusion. This may result in an injurious systemic inflammatory response that becomes perpetuated with vascular disease progression.

Aim: To assess the inflammatory response of simple exercise, of claudication, and of increasing category of PVD in terms of the markers of ischaemia reperfusion type injury.

Methods: Seventy-five patients were enrolled in this experimental study. Data were collected from 22 patients with grade 0 claudication (controls), 28 patients with grade 1 claudication, and 25 patients with grade 2 claudication (SVS/ISCVS [Society for Vascular Surgery/International Society for Cardiovascular Surgery] classification). Levels of plasma neutrophil elastase, total antioxidant capacity (TAC), the urine albumin to creatinine ratio (UACR), and neutrophil CD11b expression were determined after rest. The claudicants and control groups then underwent standardized treadmill exercise, after which the above markers were re-measured at 5, 30 and 60 minutes from the test.

Statistics: Data are treated as non-parametric. The Mann–Whitney *U* test is used for inter-group comparison.

Results: There was no significant difference in resting TAC between the three groups. Grade 2 claudicants had significantly higher baseline urine albumin leak ($P<0{\cdot}01$), and CD11b expression ($P<0{\cdot}01$), compared to the control group and grade 1 claudicants. Exercise caused significant increases in neutrophil CD11b ($P<0{\cdot}01$), and neutrophil elastase ($P<0{\cdot}01$), that were not seen in controls.

Resting measurements of inflammatory markers according to category of PVD

Category of PVD	Number	TAC	Neutrophil CD11b Mean channel fluorescence	UACR mg/mmol
Grade 0	22	720 (630–858)	2·53 (2·17–3·2)	0·49 (0–1·3)
Grade 1	28	813 (636–909)	3·08 (2·38–3·9)*	1·96 (0·86–3)*
Grade 2	25	765 (400–980)	11·5 (7·3–15·2)†	6·4 (1–7·5)†

*$P<0{\cdot}05$ Mann–Whitney U test vs control group.
†$P<0{\cdot}01$ Mann–Whitney U test vs control group.

Conclusion: Increasing severity of PVD is associated with systemic inflammatory changes. These changes are also seen episodically in claudicants during exercise, and may contribute to the progression of their vascular disease.

Polymorphism of apolipoprotein E genotype in patients with iliofemoral and femoropopliteal reconstruction followed by restenosis

G. Vallus, B. Dlustus, Gy. Tóth, Á. Baranyai, *B. Nagy and *I. Karádi *Department of Vascular Surgery, Central Military Hospital, Budapest H-1134 Róbert K. krt. 44.*
**Semmelweis Medical University, Budapest, Hungary*

The risk factors in restenosis after peripheral vascular reconstructions are very different including technical errors, neointimal proliferation, thrombotic factors, haemorrheological components, diabetes, hypertension, renal diseases and smoking.

The aim of this study was to investigate the genetic alterations of apolipoprotein E, which is a main determinant of lipoprotein metabolism under physiological and pathophysiological conditions, respectively.

A group of 107 patients (70 male and 37 female, aged 39–78 years) with severe peripheral vascular atherosclerosis and early (within 6 months) or late (after 12 months) restenosis after vascular reconstruction were examined. Blood was taken after 12 h fasting in supine position for determination by enzymatic method of serum cholesterol and triglycerides, determination by precipitation technique of HDL-cholesterol, and for immunological detection of apolipoproteins. Leukocyte DNA was prepared for the detection of apolipoprotein E genotypes and F4 and F5 primers were used to PCR amplification followed by HhaI enzymatic digestion and gelelectrophoresis. Blood donors (n=253) served as controls.

Significantly elevated serum cholesterol [6·4 (1·3) vs 5·5 (1·1) mmol/L, P=0·0001] and serum triglyceride [2·2 (1·7) vs 1·5 (0·8) mmol/L,

P=0·0001] level was found in the patients compared to controls. There was no difference in HDL-cholesterol level between the two groups [1·1 (0·62) vs 1·0 (0·3) mmol/L, P=0·1]. A preponderance of apolipoprotein E 3/4 (26/107 24·5 per cent vs 37/253 14·6 per cent, P=0·02, Fisher's Exact Test) was detected in the whole atherosclerotic group with restenosis compared to control population. In patients with early restenosis compared to those with late restenosis, no difference in the distribution of apolipoprotein E genotypes was found.

In conclusion, besides lipoprotein lipids and other metabolic components, apolipoprotein E 3/4 may play a pivotal role as risk factor for restenosis in peripheral vascular atherosclerotic disease.

Endoscopic venous surgery for incompetent perforators

R. Vohra and S. Odogwu *Selly Oak Hospital, University Hospital Birmingham NHS Trust, Raddlebarn Road, Birmingham*

A pilot study assessing the efficacy of subfascial endoscopic ligation of incompetent venous perforators in 20 patients was undertaken.

Patients and methods: There were 15 females and five males with an average age of 68 and 52 years respectively. The indications for surgery were lipodermatosclerosis in 16, eczema in 11 and non-healing ulcers in six patients. All patients had incompetent venous perforators diagnosed with colour flow Duplex Doppler and phlebography. The operation was carried out through a single port using the Olympus SEPS system in an avascular field under a tourniquet. The average operating time was 45 minutes. Seven patients had adequate superficial venous surgery previously whereas 11 had conjunctional superficial venous surgery with SEPS. One patient had no associated junctional venous incompetence.

Results: The operation was successfully carried out in all but one patient. There were 22 legs and 29 sites in 19 patients. Incompetent perforators were found in 21 medial and eight lateral sites: 1–3 perforators ligated in 18, 3–5 perforators in six and 5–7 perforators in five sites. Active lipodermatosclerosis improved in 15/17 patients and venous ulcers healed in 4/6 patients. Skin eczema and aches/pains were cured in all. The average hospital stay was 2·6 days. Early complications occurred in three patients; haematoma in one and wound infection in two. All three patients having recurrent skin problems had significant missed perforators which were ligated in the second sitting.

Conclusions: This study has shown that subfascial endoscopic ligation of venous perforators can be performed effectively with a low incidence of complications. There is, however, a learning curve as all three patients with missing perforators were in the first half of the study.

Is determination of the lowest level of amputation with transcutaneous oxygen better than empiric estimation?

L. Vrtík, Labaš, B. Ohrádka, F. Zernovický and J. Simo
University Hospital, Bratislava, Slovak Republic

In our study we evaluated patients before leg amputation. The patients were divided in two groups: group 1 (382 patients) – the amputation level was estimated by empiric experiences; and group 2 (59 patients) – the amputation level was estimated by measuring of transcutaneous oxygen ($PtcO_2$). In group 2 we followed importance of Doppler examination (ankle-brachial pressure index, ABPI), palpable pulse near the amputation level, regional perfusion index (RPI) and transcutaneous oxygen ($PtcO_2$). We evaluated the importance of haemoglobin and albumin as predictive factors of stump healing in both groups.

In empiric group (382 patients) the number of reamputations was 84 patients (22 per cent) and in oxymetric group the number of reamputation was four patients (7 per cent) – three times lower and with statistical significance. Comparing of sensitivity, specificity and effectivity of ABI, palpable pulse, RPI and $PtcO_2$ we found out that the most important value for estimating propriate amputation level has RPI and $PtcO_2$. Critical value of $PtcO_2$ is 28 torr.

The level of albumin (Alb >40 g/l) has statistical significance and we can consider it as a predictive value of stump healing. The patients with this value of albumin before amputation had four times lower number of reamputations. We did not find out statistical significance in haemoglobin.

Conclusions: 1. The most probable healing of the stump is in the vicinity of palpable pulsation. 2. The most probability of stump healing have patients with Alb >40 g/l. 3. Healing of the below knee stump has the highest probability at ABI >0·45. 4. Critical value for practically complete stump healing is for $PtcO_2$ >28 torr as well as RPI >0·6 immediately above the level of amputation.

Patients referred from national centres to a single centre for consideration for endovascular abdominal aortic aneurysm repair: reasons for referral and rejection

S.R. Walker, S.W. Yusuf, M. Armon and B.R. Hopkinson
Department of Vascular and Endovascular Surgery, Queens Medical Centre, Nottingham, UK

Aims: The referral pattern of patients with abdominal aortic aneurysms (AAA) to a single centre has changed following the introduction of endovascular repair (EVR) of AAA. We aim to show this change and the reason for referral and rejection for EVR of AAA.

Method: A retrospective study of all elective referrals of patients with AAA to a single centre over a three year period.

Results: Three hundred and sixty five patients were referred over the study period. The proportion referred from national centres for EVR increased over the study period. One hundred and ten patients were referred from national centres. The commonest reason for referral was that the patient was at high risk at open repair due to ischaemic heart disease (n=37). Of the 110 patients, 63 subsequently underwent EVR of whom 54 are still alive after a median follow-up of 11·8 months. The reasons for rejection for EVR are divided into anatomical and others. The commonest anatomical reason for rejection was that the proximal neck was too short (n=8) and in the other group, the commonest reason for rejection was that the patient was unfit for a general anaesthetic (n=3). Of those rejected (n=47), 10 have undergone open procedure in their referring hospital and 33 have not had any surgery.

Conclusion: There has been an increase in the number of referrals of patients with AAA from national centres although not all are suitable for EVR.

A prospective, double-blind, placebo-controlled crossover study to assess the effect of sublingual glyceryl trinitrate on the ABPI, claudication and maximum walking distance in patients with intermittent claudication

S.R. Walker and S.T. MacSweeney *Department of Vascular and Endovascular Surgery, Queens Medical Centre, Nottingham, UK*

Aim: To assess the immediate effect of sublingual glyceryl trinitrate (GTN) on the ankle brachial pressure index (ABPI), claudication distance (CD) and maximum walking distance (MWD) in patients with intermittent claudication.

Method: Inclusion criteria: I) history of intermittent claudication; II) resting ABPI of 1 or less; III) fall in ABPI of greater than 0·1 following exercise. Patients already on nitrates were excluded. Study 1. Following randomization to receive either 800 micrograms of sublingual GTN or placebo, patients (n=25) underwent a standardized exercise test. The post exercise ABPI was recorded. The crossover part of the study was then performed. Study 2. Patients (n=22) were exercised to their limit of tolerance at 3·2 km/h and their CD and MWD were measured. They were then randomized to either GTN or placebo spray and the exercise test repeated, recording the CD and MWD, followed by the crossover part of the study. Statistical analysis was by Wilcoxon Matched Pairs Signed Ranks Test.

Results:

		Placebo (median)	GTN (median)	*P*
Study 1	Post exercise ABPI	0·29	0·36	0·0001
Study 2	CD (IQ range)	70 m (50–80)	70 m (50–85)	0·5883
	MWD (IQ range)	105 m (80–172)	125 m (95–167)	0·0084

Conclusion: Sublingual GTN decreases the fall in ABPI following exercise and increases the maximum walking distance.

Can a measuring angiogram be used in place of a CT scan in the measurement of proximal neck dimensions in patients with ruptured AAA undergoing endovascular repair

S.R. Walker, B. Braithwaite and B.R. Hopkinson *Department of Vascular and Endovascular Surgery, Queens Medical Centre, Nottingham, UK*

Aim: The management of patients presenting with ruptured abdominal aortic aneurysms (AAA) can be delayed in the process of gaining accurate proximal neck dimensions by computerized tomography (CT). Is it feasible to obtain these measurements by an on table measuring angiogram?

Methods: Fifteen patients undergoing elective endovascular repair of AAA had both preoperative spiral CT and on table measuring angiograms. The angiograms were reviewed blindly by two vascular registrars who measured proximal neck diameters and lengths. The mean of these measurements was compared to the CT dimensions. They then suggested the diameter of the proximal graft and whether or not a supra renal uncovered stent would be required. These results were compared to the actual size and configuration used.

Results: The mean maximum neck diameter as measured by the registrars was on nine occasions less than that on CT, on three occasions more than that on CT and on two occasions tied (P=0·09 Wilcoxon Matched Pairs). In eight patients the neck length was measured too short and in seven cases measured too long when compared to CT. This resulted in registrar 1 undersizing the graft in six cases, but equal or over sized in nine, and registrar 2 undersizing in four cases and equal or oversizing in 11. It also resulted in registrar 1 not using a supra renal stent in three cases as opposed to registrar 2 not using a supra renal stent in two cases in patients who did require these.

Conclusion: On table angiograms are poor at estimating neck length and emergency grafts should therefore have an uncovered supra renal stent. To oversize the proximal graft is better than to undersize. In 60–70 per cent of cases an appropriate graft size can be estimated from the on table angiogram alone.

Radiation exposure of the surgical team undertaking endovascular repair of abdominal aortic aneurysms

S.R. Walker, J. Lloyd, S.W. Yusuf and B.R. Hopkinson
Department of Vascular and Endovascular Surgery, Queens Medical Centre, Nottingham, UK

Aims: The addition of endovascular techniques to the skills of a vascular surgeon may pose a risk of increased radiation exposure. We aim to quantify this risk and screening times with endovascular repair (EVR) of abdominal aortic aneurysms (AAA).

Method: Part 1. A retrospective study on the X-ray screening times of 140 cases of EVR of AAA. The type of graft used and the presence of a radiologist was recorded. The procedure was divided in those early and late in our experience of EVR of AAA. Part 2. A prospective study on six consecutive cases of EVR of AAA where theatre personnel were equipped with body radiation dose meters. In addition, the surgeon and assistant wore an ocular meter taped to the forehead. Radiation doses were measured conventionally.

Results: Part 1. The median screening time for EVR of AAA was 24·9 minutes (IQ range 17·2–33·8). There was no apparent learning curve when screening times between late and early cases were compared. There was however a significant increase in the median screening times for aorta uni-iliac grafts when compared to bifurcated grafts (24 vs 33 minutes, P=0·012). Presence of a radiologist did not influence screening times. Part 2. All body meters had total radiation dose less than the lowest measurable limit. The occular meters recorded 0·4 mSv and 0·3 mSv for the surgeon and assistant respectively.

Conclusion: EVR of AAA can be performed with minimal radiation dosage to the theatre personnel, although screening times for bifurcated grafts are longer than for aorta uni-iliac grafts.

Blood product requirements in patients undergoing elective endovascular repair of abdominal aortic aneurysms

S.R. Walker, S.W. Yusuf, B.B. Braithwaite, R. Lonsdale, P.W. Wenham and B.R. Hopkinson *Department of Vascular and Endovascular Surgery, Queens Medical Centre, Nottingham, UK*

Aims: A prospective study was set up to investigate the effect of an endovascular programme on the blood transfusion requirements of patients undergoing elective aortic aneurysm surgery.

Methods: The blood product requirements of 132 patients undergoing elective endovascular repair using an aorta uni-iliac graft and femoro-femoral crossover (Group 1) was compared with the requirements of 35 patients undergoing conventional open repair (Group 2) and 37 patients undergoing femorofemoral crossover grafts alone (Group 3). Blood transfusion requirements were determined by intraoperative blood loss, clinical indication and postoperative haemoglobin concentration. Results are expressed as median (range).

Results:

	Blood loss (mls)	Number of units blood transfused
Group 1	500 (400–5500)	2 (0–38)
Group 1a (uncomplicated n=120)	500 (400–1500)	2 (0–12)
Group 1b (complicated n=12)	1550 (500–2900)	6 (0–38)
Group 2	1500 (400–5500)	3 (0–19)
Group 3	500 (200–1000)	0 (0–6)

Conclusion: Although measured blood loss is less in Group 1 this is not reflected in the use of blood products. Patients undergoing endovascular repair who require additional interventions were the highest consumers of blood products.

Assessment of patency rate and intimal hyperplasia in Heparin coated small vascular grafts

B.H. Walpoth, R. Rogulenko, E. Rogulenko, T. Schaffner and U. Althaus *Thoracic and Cardiovascular Surgery and Pathology, University of Berne, Switzerland*

Aims: Intimal hyperplasia (IH) represents a major cause of late failure in vascular grafts. Heparin shows a beneficial effect on long-term patency and prevents progression of intimal hyperplasia. Our aim was to assess patency rate and intimal hyperplasia formation in small calibre vascular grafts coated with Heparin.

Method: In 40 rats an infrarenal aortic interposition graft was implanted using sterile and microsurgical techniques. Two different types of graft were tested (Gore-tex and proprietary polyurethane [PU]) with and without Heparin coating. All animals survived 8 weeks after implantation. Area and volume of intimal hyperplasia and the per cent stenosis at the anastomoses and in the graft were measured.

Results: Untreated grafts showed a patency rate of 70 per cent for Gore-tex and 60 per cent for PU grafts. Heparin coated grafts showed 100 per cent patency in the Gore and 90 per cent patency in the PU group. All grafts showed intimal hyperplasia mainly at the anastomoses and it was significantly more pronounced in native PU than Gore-tex graft ($P<0\cdot05$). Heparin coating reduced significantly intimal hyperplasia at the anastomosis; namely 42 per cent for Gore-tex and 55 per cent for PU grafts.

Conclusions: Small grafts show an enhanced intimal hyperplasia at the graft anastomoses after eight weeks of implantation. Gore-tex grafts show significantly less intimal hyperplasia yielding a better patency rate. Heparin coating reduces significantly overall graft thrombosis but had no significant overall effect on intimal hyperplasia. Thus, Heparin coating seems to be beneficial for graft patency.

Patient benefit of cell washing during cardiac surgery

B.H. Walpoth, N. Eggensperger, N. Walpoth-Aslan, P. Neidhart, M. Lanz, P. Spaeth and U. Althaus *Thoracic and Cardiovascular Surgery, Anaesthesia and Central Laboratory of the Swiss Red Cross, University of Berne, Switzerland*

Aims: Our aim was to influence the systemic inflammatory response syndrome (SIRS) during cardiac surgery by washing the autologous activated cardiopulmonary bypass (CPB) blood before retransfusion to the patient.

Methods: In a prospective randomized study CPB blood of 10 patients was processed by cell washing (CATS: Fresenius AG, Bad Homburg) or retransfused directly to 10 control patients without processing. Blood volume, processing time, haematology, blood chemistry, complement, coagulation and cytokine measurements were performed before and after CATS processing and before and after retransfusion to the patient on the ICU. Patient's outcome and adverse events were analysed.

Results: Mean values ± 1 SD of unprocessed (control) and washed (CATS) CPB blood.

Parameter	Control	CATS
fHb (mg/dl)	181·8±50·1	11·6±3·7
Heparin (IU/ml)	15·5±6·7	0·1±0·1
Prothrombin F1+F2 (nmol/l)	26·4±12·7	1·0±0·7
D-Dimers (mg/l)	28·5±15·4	1·7±1·5
C3a (ng/ml)	4731±2970	<269·5±32·6
C5b-9=TCC (ng/ml)	1993·7±479·1	<33·8±51·8
Il-6 (pg/ml)	1036·2±1245·2	30·7±22·4
Il-8 (pg/ml)	37·1±35·4	11·7±7·5

The washed autologous CATS concentrate yields a high transfusion effect (hematocrit 0·24 → 0·62) with a significant reduction of activated blood products (elimination rate >94 per cent; $P<0\cdot001$). In the control patients a transient significant elevation of the heparin concentration (0·1±0·5 – 1·5±0·7 IU/ml), plasma haemoglobin, complement (C3a/TCC) and cytokines (Il-6) was noted after retransfusion of unwashed blood. Three patients of the control and two patients of the CATS group showed postoperative adverse events which correlated to their intraoperative high mediator levels.

Conclusions: Blood washing with the CATS system yields a high quality autologous red cell concentrate. Due to the significant reduction of activated blood products a trend to reduce SIRS in the patient after cardiac surgery with cardiopulmonary bypass could be demonstrated.

Major lower limb amputation for vascular disease: outcome after rehabilitation

P. Williams, K. Rashid and R.J. Cuschieri *Doncaster Royal Infirmary, Armthorpe Road, Doncaster, South Yorkshire, UK*

Major lower limb amputation is often associated with poor outcome in terms of mobility. However, patients' initial mobility when measuring outcome is often not taken into account. The aim of the study was to investigate the final outcome when compared with preoperative mobility status. Eighty consecutive patients under the care of one surgeon who required major lower limb amputation for non-reconstructible occlusive arterial disease were studied. Prior to surgery mobility was assessed by the same physiotherapist (PW) using a modified Harold Wood Mobility Score. A detailed medical and surgical history was also taken. All patients were assessed for a prosthesis. Rehabilitation was maintained after no further benefit was deemed achievable. Mobility scores were again taken at the end of this period.

Sixty-one patients (77 per cent) were over the age of 65 and 26 patients (32 per cent) had diabetes. Twenty-five patients (31 per cent) had previous attempts at vascular reconstruction. Fifty-one per cent of patients had an above knee amputation while 46 per cent had a below knee amputation. Stump healing was a problem in 65 per cent of below knee amputations with a revision rate was 13 per cent. Twenty-nine per cent of patients died within three months of surgery. Prior to amputation 64 per cent of patients were housebound and 26 per cent were confined to a wheelchair due to pre-existing conditions. Postoperative scores show that 29 patients (57 per cent) of surviving patients were successfully rehabilitated to their preoperative status. Empirically derived mobility scores may not be an ideal measure of outcome and social, psychological and functional factors need to be taken into account.

Clinical behaviour and tumour risk factors for the prognosis of resectable ampullary carcinomas

F.J. Briceño, F. Alba, P. Lopez-Cillero, G. Solorzano,
E.A. Barker, G. Miño and C. Pera *Department of Surgery,
Hospital Reina Sofia, Cordoba, Spain*

Aims: The purpose of this study was to analyse long-term prognosis after pancreaticoduodenectomy (PD) for ampullary carcinomas relative to clinical factors, nuclear composition and oncogenes.
Methods: Twenty-four consecutive patients with ampullary carcinomas who underwent PD between 1993 and 1996 participated in this study. Clinical variables included sex, age, duration of symptoms, alanine aminotransferase (s-ALT), aspartate aminotransferase (s-AST) and alkaline phosphatase. Morphological variables were tumour size, histological type, tumour differentiation, adenoma content and local lymph node invasion. Cell-cycle composition was evaluated with ploidy, percentage of phase 'S' cells and DNA index (DI). Proliferation markers included Cathepsine D in tumour and stroma, SPF tyrosin-kinase, Ki67 antigen, Topoisomerase II, erbB-2, EGFR, p53, CD31, bcl-2 and nm23. Multivariate survival analysis was obtained with Cox's regression proportional hazard model with these factors as covariates.
Results: Patient survival at 1 month, 1-, 2-, 3 yrs was 100, 92, 84 and 76 per cent. Cox's proportional hazard model revealed that a short duration of symptoms, tumour size, preoperative s-AST and DNA Index were independently correlated with a dismal prognosis:

Covariates	b coefficient	Significance	Hazard
Duration of symptoms (months)	−2·1881	0·0358	1·12
Tumour size (cm)	2·1937	0·0327	8·96
Preoperative s-AST (per 100 Units)	0·26	0·0768	1·3
DNA Index (DI)	3·2117	0·0436	24·82

Conclusions: Most of the tumour markers evaluated did not affect patient survival. However, DNA Index showed independently a strong risk increase. Since duration of symptoms and s-AST were associated with a low risk-increase, tumour size enhanced mortality risk eight times.

Endoscopic vs surgical biliary drainage for non-resectable ampullary carcinomas

F.J. Briceño, F. Alba, J. Gomez-Barbadillo, P. Lopez-Cillero,
G. Solorzano, F.J. Padillo, G. Miño and C. Pera *Department of
Surgery, Hospital Reina Sofia, Cordoba, Spain*

Aims: The objective of this study was to compare endoscopic vs surgical management respect short- and long-term outcome for non-resectable ampullary carcinomas.
Methods: We designed a prospective and randomized trial in which 52 consecutive patients since 1990 to 1997 with non-resectable ampullary carcinomas were treated. Non-resectability criteria included: age >75 yrs, morbid obesity, distant metastases and complete obstruction of the portal vein. Twenty-four patients underwent surgical drainage (hepatico-jejunostomy – 21, ampullectomy – 3). A definitive biliary endoprothesis was placed in the remaining 28 patients. Both groups were well-matched for sex, age, duration of symptoms, preoperative/pre-endoscopic serum bilirubin, alanine aminotransferase (s-ALT), aspartate aminotransferase (s-AST) and alkaline phosphatase. The mean follow-up was 14 months. Survival analysis was performed by Kaplan–Meier method and compared by log-rank test. Postoperative hospital stay and complication rate were compared by analysis of variance.
Results: Patient survival at 1-, 6-, and 12 months were 92, 84 and 48 per cent in the 'Surgery group', respectively; and 88, 76 and 34 per cent in the 'Endoscopic group'. There were no statistical differences respect overall survival (log-rank 0 3·47; P=0·062). Postoperative complication rate in the surgical group was 7/24 (29 per cent) and 7/28 (25 per cent) in the endoscopic group (P=0·24). Patients with endoprothesis showed a shorter hospital stay (6·2±1·1 vs 10·4±2·8 days; P<0·05).
Conclusions: Endoscopic biliary drainage is an adequate procedure in the management of non-resectable ampullary carcinomas, with similar survival and complication rate respect surgical treatment, and with a shorter hospital stay.

Congenital malformations of the gallbladder in the laparoscopic era

M.A. Carbajo, J.C. Martín, J.I. Blanco, C. Cuesta, J.A. Guerro,
J. Mato, C. Vaquero and R. Atienza *Department of Surgery,
Medina del Campo Hospital, 47400 Medina del Campo,
Valladolid, Spain*

Aim: The main objective is to determine the incidence of congenital malformations in surgery of the gallbladder because of the high risk of iatrogenic damage that may occur.
Methods: In a period of five years between November 1992 and November 1997, 470 laparoscopic cholecystectomies were performed, studying the described congenital malformations and the operative incidence of anatomical anomalies.
Results: There were congenital malformations in the 1·7 per cent of the cases: 1 agenesis of the gallbladder and cystic duct; 1 misplaced left lobe; 3 gallbladder hypoplasias (congenital vesicle diverticulo); 2 implants of the cystic in the right hepatic tract and 1 in the left. Moreover, 9 anomalies of the cystic artery (1·9 per cent) were diagnosed. All of them were intraoperative discoveries. Two patients were converted for anatomic verification. There were no intraoperative complications.
Conclusions:
1. One has to bear in mind the possibility of congenital malformations which has not been diagnosed previously.
2. In these cases the probability of injuring or cutting the extrahepatic biliary tracts is very high.
3. In case of anatomic incomprehension, conversion to open cholecystectomy is advised.

Bile peritonitis caused by congenital choledochal cyst perforation in an 8-month-old child: case report

V. Cingel, F. Horn and J. Babala *Department of Paediatric
Surgery, School of Medicine, Comenius University, University
Children's Hospital, Limbova 1, 833 40 Bratislava, Slovakia*

Aim: Bile peritonitis caused by congenital choledochal cyst perforation is a very rare surgical condition. This paper presents the experience acquired in diagnosis and surgical management of one infant.
Patient and methods: An 8-month-old male had been conservatively treated at the regional hospital for collapse, subsequent intermittent abdominal pain and vomiting for 5 days. On admission to our department he had fever and his abdomen was moderately distended with mild tenderness. Laboratory studies showed slightly elevated levels of total and conjugated bilirubin and SGOT. Abdominal ultrasound showed ascites. The diagnosis of generalized peritonitis was established and laparotomy was performed. Biliary peritonitis caused by congenital choledochal cyst perforation was found peroperatively. Because of established biliary peritonitis and the general clinical condition of the patient, external drainage was done via T-tube inserted through the perforation. Cholangiography 18 days after the operation confirmed type I choledochal cyst. A definitive operation, total cyst excision and Roux-en-Y hepaticojejunostomy (end-to-side) was performed one month after stabilization of the clinical status.
Results: There were no postoperative complications. Currently, he has been followed up for 20 months and is doing well.
Conclusions: Spontaneous perforation of a choledochal cyst is a very rare complication. Diagnosis is usually delayed due to nonspecific clinical manifestations and its exact establishment occurs mostly peroperatively. An external drainage of the bile via a T-tube is a preliminary procedure when urgent decompression is necessary. Subsequent total cyst excision and Roux-en-Y hepaticojejunostomy on an elective basis is the definitive surgical treatment.

The effect of vitamin E on plasma and liver free radicals in obstructive jaundice

A. Çökmez, C. Akaoğlu, S. Gür, B. Taşkın, Ö. Sayın, O. Karabağ, O. Nazlı and S. Deniz *İzmir Atatürk Training Hospital, 1st Surgery Department, İzmir, Turkey*

Objective: To observe the alterations of the free O_2 radicals in plasma and liver, and also the effects of vitamin E (α-tocopherol) – a strong antioxidant – to this alteration in obstructive jaundice.
Design: Experimental laboratory study.
Setting: Aegean University department of experimental surgery, Turkey.
Subjects: Twenty male Wistar rats.
Interventions: Through an upper midline incision a ligature was passed around the common bile duct in the sham-operated control group. In the group 2, the common bile duct was ligated with 4·0 silk and divided. Finally in group 3, the common bile duct was ligated and a subcutaneous dose of 20 mg/100 g body weight/day of vitamin E administered (Ephynal, Roche® – Turkey) from the 1st postoperative day for 15 days.
Main outcome measures: Plasma and liver malondialdehyde (MDA) – an available marker of free radicals and lipid peroxidation – were measured after 16 days of initial operation.
Results: Plasma and liver MDA values from group 2 [8·320 (1·360) nmol/ml–5·940 (0·776) nmol/ml] were significantly higher than the MDA values obtained from group 1 [2·573 (0·389) nmol/ml–3·544 (0·386) nmol/ml] ($P<0·005$, $P<0·005$). Although the plasma and liver MDA values of group 3 [4·680 (1·120) nmol/ml–5·219 (0·780) nmol/ml] were reduced remarkably when compared to group 2 [8·320 (1·360) nmol/ ml–5·940 (0·776) nmol/ml], it was not significant ($P>0·05$, $P>0·05$).
Conclusions: In this experimental study, significant elevation of MDA in plasma and liver suggest free radicals to be an effective factor in the pathogenesis of the hepatocyte injury in cholestasis. On the other hand, administration of vitamin E – one of the most effective antioxidant ever known – makes the increased plasma and liver lipid peroxide values to be reduced but this is not significant.

Intraoperative choledochoscopy as an alternative to intraoperative T-tube cholangiography in detecting retained stones in the biliary tree

A. Csengeri, M. Zwick and G.Y. Takacs *Department of Surgery, General Hospital, Subotica, Yugoslavia*

The aim of the study is to evaluate the success of the intraoperative choledochoscopy in detecting retained stones after classical cleaning of the bile ducts and to evaluate if its always necessary to perform intraoperative **T**-tube cholangiography to lower the incidence of retained calculi.

Since 1993, when we started with choledochoscopies till 1997, 153 choledochotomies were performed for choledocholithiasis. The patients were selected in three groups: in the first, only **T**-tube cholangiography was performed (87 cases), in the second only choledochoscopy (52 cases) and in the third group of 14 patients choledochoscopy was followed by **T**-tube cholangiography. Fifty per cent dilution of Telebrix were used for cholangiography. An Olympus T-20 fibercholedochoscope with 6 mm tip was used for the inspection of the biliary tree. In the first group, retained stones was found on postoperative **T**-tube biligraphy in 6 (6·9 per cent) patients, in the second group in 1 patient (1·9 per cent). In the third group no residual stone occurred. With choledochoscope we found in 46 per cent of cases more calculi after classical cleaning of the biliary tree. Choledochoscope was useful in the extraction or luxation of impacted calculi in the region of the papilla in 98 per cent, when these stones cannot be moved with other manipulation.

We conclude that in experienced hands intraoperative checking of the biliary tree with flexible choledochoscope is as effective as **T**-tube cholangiography. Lowering the duration of the operation and radiation exposure of the operating team is another advantage of this procedure.

Cellular and humoral immunity in the acute calculous cholecystitis

B. De Andres, J. Glez.-de-Zárate, R.A. De Andres, J. Rabadan, R. Bustamante and J. Bustamante *Departamento de Cirugia, Facultad de Medicina, Universidad de Valladolid, c/ Ramon y Cajal nº 7, 47005 Valladolid, Spain*

Aim: The acute calculous cholecystitis is an acute inflammatory disease and to us seems a good model to study certain immunological parameters of response inflammatory of non-infectious origin.
Materials and methods: Following institutional ethics committee approval from Universitary Hospital of Valladolid and informed consent of patients, blood samples were obtained from 20 patients with acute calculous cholecystitis (Group 1). All blood samples were taken on the 1st day of diagnosis. A group of 20 volunteers served as controls (Group 2). The levels of TCD8, TCD4 and B lymphocytes, NK cells, immunoglobulins (Ig) G, M, A and IL-2 receptor (RIL-2) were measured in blood by flow cytometry, nephelometry and ELISA, respectively. The acute calculous cholecystitis diagnosis was performed by clinicals signs and symptons and the cholelithiasis by ultrasonography. Statistical analysis of data was performed using ANOVA-test and the Pearson-correlation test between groups, P-value <0·05 was considered significant.
Results: Groups were comparable in terms of anthropometric characteristics. Results are shown in the following table:

	Group 1	Group 2	Significance
TCD8 cells (%)	26·6±9·5	36·6±11·1	$P<0·05$
TCD4 cells (%)	39·8±11·1	40·9±10·2	NS
B lymphocytes (%)	13·9±6·4	8·1±3·4	$P<0·01$
IgG (UI/ml)	136·5±37·6	146±31·6	NS
IgM (UI/ml)	127·5±63·4	176±69·4	$P<0·05$
IgA (UI/ml)	202·6±89·8	169±51·4	NS
RIL-2 (pM)	141·2±81	57·6±28	$P<0·01$

Conclusions: RIL-2 which is the major growth factor for T-lymphocytes and the quantity of RIL-2 synthesized determines the size of the T-cell-dependent immune response. has an abrupt increase from the first day of acute-cholecystitis diagnosis.

Early repeat operations after gastric resection for peptic ulcer disease

K. Dimitrova, I. Ratchev and R. Gudzenko *Russe, No 56, Pleven 5800, Bulgaria (Med. Dr. K. Dimitrova)*

Presented are a 12-year follow-up of patients with repeat operations after gastric resection by Bilroth I and Bilroth II for peptic ulcer disease. The reasons for the repeat operations were: (1) diffuse peritonitis (duodenal vault insufficiency or anastomosic leak); (2) intra-abdominal abscess (subphrenical, subhepatic); (3) eventeration; (4) intra-abdominal haemorrhage or haemorrhage in the gastric lumen (poor haemostasis, stress ulcers, haemorrhagic gastritis, ulcer remnants etc.); (5) early ileus; (6) lack of patency in the anastomosis – stenosis, anastomositis, outside pressure etc.; (7) acute postoperative pancreatitis; (8) complications from the biliary tree; (9) others.

The following surgical interventions were carried out: re-laparotomy, haemostasis, lavage, resection, debridment, gastro-intestinal anastomosis. Good results were observed. Only nine patients died.

We can reach the following conclusions from the results:

1. Re-laparotomies were 4·7 per cent from our cases.
2. The most frequent indication for re-laparotomy was postoperative pancreatitis, haemorrhage end diffuse peritonitis.
3. Mortality among the re-operated patients was 33·3 per cent.
4. Laparostomy and programmed lavage is recommended as a way of reducing mortality.

Operative internal drainage of bile ducts

Z. Górka, J. Nowak, M. Olakowski, Z. Gruszka, J. Kabat and P. Lampe *Department of Digestive Surgery, Silesian Academy of Medicine, 14 Medyków st., 40-752 Katowice, Poland*

Reconstructing operations, performed on extrahepatic bile ducts, usually need protection of anastomosis by means of drainage. Classic Kehr's drainage is loaded by risk of complications. Since 1993 the authors have been applying the alternative way of drainage: an intraduodenal drainage by endoprothesis Y (DEY). Endoscopical removing of the drain was performed in 3–4 months after the operation. This way of drainage was used between March 1993–May 1997 in 23 patients. We did not observe any complications or pancreatic reactions. Clinical control of patients was made after operation with ECW. In four cases the late results of treatment were unsuccessful. In the other 16 patients the results of performed operations were favourable.

Conclusion: Proposed way of protection of bile ducts reconstructions using (DEY) we noticed fewer complications in comparison with analogus group of patients protected by classic Kehr's drainage.

Keywords: Iatrogenic diseases, drainage bile ducts, common bile ducts (CBD).

Acute dilatation of the choledochal cyst masquerading as an acute abdomen

N.A. Kama, T. Coskun, U. Gozalar, M. Guler, B. Kulah and M. Kebapcioglu *Ankara Numune Hospital, 4th Department of Surgery, Ankara, Turkey*

Introduction: The choledochal cyst is the predominant feature of a constellation of anomalies involving the pancreatobiliary system. The classic symptom complex of pain, mass, and jaundice is in fact encountered infrequently. This is a case of a 26-year-old pregnant woman presenting with acute dilatation of choledochal cyst masking acute abdomen.

Case report: The patient was admitted to emergency department with symptoms of severe abdominal pain, nausea and vomiting of 2 days' duration. In laboratory studies, liver enzymes, direct and indirect bilirubin levels were found to be high, while amylase and lipase levels were normal. She had abdominal guarding and rebound tenderness on all quadrants in physical examination. Abdominal ultrasonography revealed a distended gallbladder with thicken wall but without gallstones, and a cystic lesion, 5 cm in diameter, located behind the head of the pancreas. The patient underwent emergency laparotomy with a preoperative diagnosis of acute acalculous cholecystitis. During laparotomy type I choledochal cyst and annular pancreas was found. Since the patient was pregnant and no real cause of acute abdomen was found, the abdomen was closed without performing any procedure for further investigation. Further ultrasonographic examinations revealed a rapid increase in the diameter of the cyst, reaching 12 cm in 5 days and detected debris at the bottom of the cyst. Obstruction of the cystic outlet and acute dilatation of the cyst was suggested to be the cause of severe symptoms and signs. Since the patient had ongoing severe abdominal pain, percutaneous drainage of the cyst was thought to be appropriate for symptomatic relief. Pain relief was obtained immediately after the drainage of the cyst. Meanwhile preterm labour occurred. Cystography performed by means of a pig-tail catheter after the preterm labour showed the complete obstruction of the cystic outlet. After a week of drainage, ERCP was performed but the possible relation of the cyst with pancreatic duct could not be shown, probably because of the persistent obstruction. ERCP was repeated in 10 days and showed the choledochal cyst opening directly into the main pancreatic duct. The patient underwent laparotomy for definitive treatment. Since the cyst had intrapancreatic extension, pylorus preserving pancreaticoduodenectomy was performed to resect all of the lesion.

Conclusion: Choledochal cysts usually fail to contract, resulting in poor emptying and significant stasis of bile and debris. Obstruction of the cystic outlet by thick bile and debris may lead acute dilatation of the cyst masquerading as an acute abdomen.

Treatment of calculous acute cholangitis: results of a surgical management

J. Hobeika, R. Houdart, M. Salmeron and J.-F. Simon *Hôpital de la Croix-St-Simon, 125 rue d'Avron, 75020 Paris, France*

Aim: This retrospective study presents the results of a complete surgical management in the treatment of calculous acute cholangitis (CAC). Its principle is to obtain rapid and complete clearance of the common bile duct (CBD) from stones avoiding thus, endoscopic sphincterotomy (ES) as primary treatment of CAC. This latter is not always easy to perform, is not available everywhere and results in about one to two per cent in acute pancreatitis. Surgical treatment is proposed as a valuable alternative to ES.

Material and methods: Fifty-four patients with a mean age of 76 years having CAC, have been operated on from 1983 to 1993. Thirty-eight (70·4 per cent) patients have been operated on as an emergency and 16 (29·6 per cent) patients between 2 and 6 days after admission. Operation consisted in obtaining rapid and complete clearance of the common bile duct (CBD) from stones, which was controlled intraoperatively by flexible choledochoscopy. CBD was then immediately closed without biliary drainage in 50 (92·5 per cent) patients. During the same period, no ES was performed as first treatment of cholangitis but one patient required this latter postoperatively.

Results: There were no postoperative deaths. Fifty-two patients (96·2 per cent) had no biliary complications and 13 (24 per cent) patients had general complications especially respiratory and cardiovascular complications. Patients were discharged from hospital 13·6 (±6·9) days after operation.

Conclusion: Despite opposite opinions, we do not advocate the use of primary ES in the treatment of CAC. The benefits of this technique is to confirm normal biliary tract anatomy, to remove the gallbladder which was found to be infected in more than 40 per cent of the patients, and to avoid ES's complications. Considering this series results, the place of surgery should be reconsidered and compared to endoscopic sphincterotomy by further comparative studies. Still, it represents a secure alternative to ES especially if ES is not easily available nor easy to perform.

Results of gallbladder carcinoma treatment using radical surgery

M. Jesipowicz, S. Rudzki, J. Jesipowicz and J. Furmaga *First Department of General and Transplant Surgery of Medical University in Lublin, 8 Jaczewskiego Street, Lublin, Poland*

Primary gallbladder carcinoma (GBCA) is generally a rare disease, but the most frequent neoplasm of extrahepatic biliary ducts and constitutes about one per cent of reasons for biliary duct surgery. Prognosis in patients coming to surgery with clinically apparent cancer is very poor. Gallbladder carcinoma spreads to the liver by direct invasion and by lymphatic vessels to periportal and pancreatico-duodenal lymph nodes. In the years 1972–1997 74 patients were treated for GBCA. Most of those patients (53) had no preoperative diagnosis of GBCA. Up to 1991 the only operation performed was cholecystectomy. Since 1991 21 patients were operated on for GBCA, in whom preoperative diagnosis was stated on a basis of clinical symptoms, USG and CT examinations and confirmed intraoperatively by histological examination. Eleven of carcinomas were found by incidental intraoperative histological examination. In 16 patients cholecystectomy and extend lymph node dissection were performed. In 7 patients only transhepatic bile duct drainage was applied. In 9 cholecystectomy and hepatic resection-segment IV and V, with extend lymph node resection were performed. Postoperative period was complicated by small bile leakage in one case with simultaneous resection of hepatic ducts bifurcation. Follow up observation period ranges from 1 to 6 years. We observed 2 to 6 months' survival in 49 patients operated on for advanced GBCA and 18 to 20 months' survival in 24 patients who underwent extend lymph node dissection or hepatic segmentectomy and extend lymph node dissection. One patient stays in our observation in very good health 6 years after segmentectomy and lymph node dissection. In our experience we can conclude that radical operation for gbca seems to be justifiable because survival of those patients is remarkably longer which is in accordance with data given by other authors.

The latest case of Mr Sherlock Holmes: the modern Dr Watsons use HCTCA!

K. Karlinger, E. Márton and P Kupcsulik* *Dept of Radiology and Oncotherapy and *1st Dept. of Surgery, Semmelweis Medical University, Budapest, Hungary*

Aim: To detect the cause of dilation of right hepatic bile ducts and a postoperative biloma after a laparoscopic cholecystectomy
Materials and methods: Laparoscopic cholecystectomy, US, US guided drainage, laboratory investigations, Helical CT Cholangiography (HCTCA)
Case report: A 33-year-old woman was treated with laparoscopic cholecystectomy in another hospital. Because she did not feel well postoperatively, she was investigated by ultrasound
Medical certificate A cystic mass in the gallblader bed and dilation of the bile ducts in the right hepatic lobe.

An ultrasound guided cystic drainage was performed and it proved the presence of a biloma Helical CT Cholangiography was recommended
The result of the investigation by HCTCA Postoperative situation Gallbladder is removed. The postoperative state is also illustrated by metallic clips. The enhancement of bile is good Bile ducts are shown well The diameter of common bile duct is normal There is some contrast material in the duodenal lumen There is considerable dilation of bile ducts in the right hepatic lobe The bile ducts in the left lobe are normal

Dr Watson performed a MIP and an SSD and gave the opinion that the right hepatic duct of atypical course had been ligated while clipping the cystic duct This led to the formation of a fistula and a subsequent biloma The passage of bile from the left lobe was unhindered, therefore jaundice was not observed
Conclusions: The surgical situation corroborated the finding of HCTCA

The so-called 'post-cholecystectomy syndrome' – a myth or reality?

R Markert, J. Wasiak, M Gryszkiewicz and Z. Muras *Clinic of General Surgery and Transplantology, Kopcińskiego 22, 90-153 Łódź, Poland*

After removal of the gallbladder 10–30 per cent of patients present with persisting various symptoms which are often called by the name of 'post-cholecystectomy syndrome'. In order to establish the cause of the complaints – 83 such patients were subjected to thorough clinical investigations, enzymatic liver and pancreas function tests, abdominal ultrasound, isotope scanning, ERCP and CT.

In 24 cases (30 per cent) the complaints related to the hepatobiliary system They were caused among other things by cholangitis or stenosis of the papilla Vateri

More frequently (in 55 cases – 67 per cent) they were due to other diseased organs, predominantly the stomach, duodenum, pancreas and large intestine The studies have shown that in 47 per cent of patients the symptoms were caused by a clearly defined disease entity
Conclusions:
1 In patients with symptoms persisting after cholecystectomy in 63 per cent can find the cause of their complaints, in 67 per cent of cases the cause was unrelated to the hepato-biliary system
2 The term 'post cholecystectomy syndrome' should not be used because it exempts ostensibly the physician from undertaking further diagnostic investigations into actual causes of patient's complaints

How can helical CT cholangiography (HCTCA) help surgeons in hunting for hidden bile duct stones?

E. Márton, K. Karlinger, P. Kupcsulik* and E Makó *Dept. of Radiology and Oncotherapy and *1st Dept. of Surgery, Semmelweis Medical University, Budapest, Hungary*

Aim: The high resolution capability of the spiral CT gave us a tool for the imaging of hidden bile duct stones and the other abnormalities of the bile ducts. Our aim was to point out the role and the place of HCTCA in the diagnostic algorithm
Materials and methods: Forty-eight patients were investigated by a spiral CT scanner. A hepatotrop contrast material was adjusted intravenously in order to reach reasonable opacification in the biliary system According to the optimal filling rates the pictures were taken delayed in two series. The pictures were evaluated in a common view and by MPR and 3D rendering MIP and SSD postprocessing methods
Results: With this method calculi were seen the common bile duct, the cystic duct, the main hepatic ducts and its secondary – and sometimes even smaller intrahepatic branches of those The bile passage toward the duodenum could be imaged in all cases.

Biliary stones were demonstrated in six cases None of them caused completed passage disturbance of the bile In two cases we could show miniature residual calculi in the little intrahepatic branches
Conclusions: In the diagnostic algorithm ultrasound has the essential role in the imaging of biliary pathologies Endoscopy seems to be tending more therapeutic than only diagnostic intervention.

According our experience the HCTCT has a main role in the differential diagnosis of bile duct dilatation We could clearly establish whether in the background of the passage disturbance was an intraductal or periductal lesion or a sclerosis of the Vater papilla

All of our cases were proved by EST or by operation

Gallbladder motility after gastric surgery estimated by infusion cholescintigraphy

M. Petrović, V. Artiko, H. Chebib, V Obradović, M Milićević and K. Kostić *Institute for Nuclear Medicine, Clinical Center of Serbia, Višegradska 26, 11 000 Beograd, Yugoslavia*

The aim of the study is the estimation of the gallbladder (GB) motility in the controls (C, n=8), patients after partial gastrectomy (Billroth I – B I, n=7 and Billorth II – B II, n=7), gastroplasty (G, n=7) and in those after total gastrectomy (PG, n=10) in order to assess the influence of the truncal vagotomy (GP, PG) and exclusion of the duodenal transit (B II, PG) of food on the GB motility

The study was performed during (3 h, 10 ml/h) infusion of 150 MBq, 0·25 mg/ml 99m-Tc-EHIDA, preceded by a loading dose. Test meal was given in 120 min

In the patients with preserved n vagus and duodenal transit (BI), ejection fraction (EF=66·4±9·2 per cent), emptying time (ET=35·1±6·2 min) and ejection rate (ER=2·1±0·5 per cent/min) were almost physiological ($P>0{\cdot}05$) (C, EF=76·7±17·9 per cent; ET=37·8±11·4 min and ER=2·1±0·45 per cent/min). In the patients with exclusion of duodenal transit (RV BII), EF values were (58·3±11·4 per cent) slightly, but not significantly decreased ($P<0{\cdot}05$) in comparison to C and RV BI while ET and ER were completely undisturbed (39·0 min and 1·61±0·46 per cent/min) In those with truncal vagotomy (GP), EF was slightly decreased (54·4±14·4 per cent), ER unchanged (1·8±0·84 per cent/min) while ET (23·3±7·5 min) was significantly ($P<0{\cdot}05$) decreased in comparison to C, RV BI and RV BII. In the PG, with both truncal vagotomy and exclusion of the duodenal transit, EF, ET and ER (23·3±8·5 per cent, 23·5±7·6 min, 0·92±0·40 per cent/min) were significantly ($P<0{\cdot}05$) decreased in comparison to C, RV BI, RV BII andGP

We can conclude that truncal vagotomy, especially if accompanied by the exclusion of duodenal transit cause GB motility disorders So, in the choice of gastric surgery, advantage must be given to the methods that preserve n vagus and duodenal transit as often as it can, in order to avoid formation of GB calculosis

Combined ERCP and laparoscopic cholecystectomy in the management of choledocholithiasis

R. Rivetti, S Tomarchio, G. Vassallo, F Lavagna, A. Ghezzo, G. Meo and L.M. Quaranta *II Divisione di Chirurgia Generale, Azienda Ospedaliera S. Croce e Carle, Via Michele Coppino, 12100 Cuneo, Italy*

The authors present a series of 70 cases of choledocholithiasis managed by removal of the common duct stones by endoscopic sphinterotomy followed by laparoscopic cholecystectomy They represent the 12 per cent of the total 600 laparoscopic cholecystectomies performed between March 1992 and December 1997. Ten cases out of 70 had to be converted to open operation.

Indications of ERCP+VLC:

(70 cases)	– Cholestasis without jaundice	30
	– Acute pancreatitis with choledocholithiasis without jaundice	18
	– Acute pancreatitis with choledocholithiasis with jaundice	4
	– Choledocholithiasis with jaundice	16
	– Ampullary stenosis	2
Converted VLC (10/70)		
	– Adhesions	7
	– Haemorrhagic complication	2
	– Duodenal perforation	1

Conclusions: The complete mini-invasive management of choledocholithiasis appears preferable to the standard open techniques.

Microlaparotomy in the management of cystic duct stump syndrome

I.I. Rozsos *Moritz Kaposi Medical Center, I Department of Surgery, Tallián Gy. u. 20–34, 7400 Kaposvár, Hungary*

Cholecystectomy is an established successful operation which provides total relief of presurgical symptoms in up to 85 per cent of patients. About 5 per cent of patients after cholecystectomy experience severe episodes of upper abdominal pain. These so called postcholecystectomy syndromes may be due to biliary strictures, retained biliary calculi, cystic duct stump syndrome, stenosis or dyskinesis of the sphincter of Oddi. Postcholecystectomy symptoms caused by cystic stump and gallbladder remnant had been described early this century. During recent years laparoscopic cholecystectomy became popular but we have not found in the literature the mention of either that it could cause cystic duct stump syndrome or it could be used for its treatment. During the last 8 years in 10 patients we found gallbladder remnants or cystic duct stumps causing their symptoms. Among the 10 patients 3 had laparoscopic and 7 classic cholecystectomy. After incomplete cholecystectomy we usually find that the cystic duct stump and the Calot triangle embedded in inflamed scar tissue. For this reason the surgical risk is too high with laparoscopic surgery to reoperate for these pathological changes. In all 10 cases the pathological cystic duct stump and gallbladder remnants were removed using 3–4 cm single microlaparotomy incisions. The postoperative stay of these patients were uneventful and they were discharged home 2–3 days after surgery.

Microlaparotomy cholecystectomy in the treatment of Mirizzi's syndrome

I.I. Rozsos *Moritz Kaposi Medical Center, I Department of Surgery, Tallián Gy. u. 20–34, 7400 Kaposvár, Hungary*

An impacted gallstone in the cystic duct with subsequent inflammation and edema resulting in extrinsic compression of common bile or hepatic duct with jaundice is known as Mirizzi's syndrome. The Mirizzi's syndrome presents a difficult surgical challenge because the dense adhesions and edematous inflammatory tissue cause distortion of the normal anatomy in Calot's triangle, leading to a great risk of bile duct injury. Therefore, a controversial issue the surgical strategy for the treatment of Mirizzi's syndrome since the introduction of laparoscopic cholecystectomy. The present study was undertaken to elucidate the applicability of microlaparotomy cholecystectomy (MLC) in the management of Mirizzi's syndrome. Between December 1990 and December 1997 we operated on 18 patients for Mirizzi's syndrome with micro and minilaparotomy. In 16 of these patients had type I of Mirizzi's syndrome, the remaining 2 had type II of this syndrome. In 15 of these patients the gallbladder was removed using 3–4 cm single microlaparotomy incisions. In the remaining 3 patients using 5·5 cm, 8 cm as well as 12 cm long incisions for the removal of the gallbladder, and placement a distal T tube because of stenosis of the common hepatic duct, suture repair of the choledochal defect as well as choledochoplasty. In the early stages, presented within seven days of the acute edema does not make MLC more difficult. In 14 of these patients the MLC were done within seven days of the onset of the obstructive cholecystitis. The postoperative stay of these patients were uneventful and they were discharged home 3 days after surgery.

Surgery of the benign biliary strictures

A. Şimşek, M. Yakut, N. Kaymakçioğlu, A. Tan, M. Bülbül, S. Çetiner and D. Şen *Gülhane Military Medical Academy, Gen. Surg. Dept., Etlik, 06018 Ankara, Turkey*

Although there have been great developments at diagnosis and treatment of biliary system surgery, benign biliary strictures are still important clinical problem. Twelve patients with biliary strictures were studied retrospectively for their diagnosis and treatment. All patients previously underwent biliary surgery and had high blood alkaline phosphatase levels. PTC and ERCP were gold standards for diagnosis of stricture site. Ten patients were diagnosed with the low level (Bismuth Grade I–II) and two of them high level (Bismuth Grade III–IV) strictures. Three of twelve patients were transferred after the laparoscopic bile duct injury. Eight patients had excellent surgical outcome in a 15-month follow-up period. Roux-en-Y hepaticojejunostomy and/or choledochojejunostomy are the best surgical procedures for treatment of benign bile duct injuries in our experience.

Preoperative ultrasound to predict technical difficulties of conventional cholecystectomy

H. Uncu, İ. Yorulmaz, Y. Aker, Y. Kaya, A. Sakarya and C. Çiftdoğan *Celal Bayar Üniversitesi Hastanesi, Genel Cerrahi A.D., 45010 Manisa, Turkey*

Ultrasonography is a safe, cheap, easy and most frequently used non-invasive radiological examination for the diagnosis of gallbladder disease. This study was designed to investigate the success of preoperative ultrasonography to predict technical difficulties of conventional open cholecystectomy.

Twenty-seven patients participated in this study on whom were performed open cholecystectomy operations. Patients who were hospitalized with the diagnosis of cholelithiasis were examinaed by ultrasound again the day before cholecystectomy. The morphology, view (distented, contracted), size, volume and wall thickness of gallbladder, number and sizes of calculi and presence of cholesterolosis, polyps in gallbladder, diameter of common bile duct, presence of pericholecystic fluid collection, appearance of the intrahepatic ducts, päncreas and liver were investigated. After the conventional cholecystectomy operations, the degree of difficulties was determined postoperatively using visual analogue scale (VAS, 0–10). The scoring was used for intraperitoneal and gallbladder adhesions, dissections of cystic artery, cystic duct and gallbladder bed. Bleeding duration of operation, using of drain and presence of complication were noted.

Gallbladder volume, number of calculi and presence of cholesterolosis were significantly associated with operative difficulties (Student's t, $P<0{\cdot}05$). The other parameters are not seen as a predictor of operative difficulties. Although preoperative ultrasound can be useful, it is not enough to predict technical difficulties of conventional cholecystectomy.

Malignant biliary tract jaundice

A. Váquez-Prado, E. Montalvá and E. Artigues *Service of General and Digestive Surgery, Valencia University General Hospital, Valencia, Spain*

Aim: After lithiasis, tumours are the most common surgically managed processes of the biliary tract. In this sense, gallbladder carcinoma predominates (80 per cent), followed by tumours of the biliary tree (10 per cent) and Vater's ampulla (10 per cent). Malignant jaundice is the most common presentation of such processes. We report our experience with this entity over a 6-year period.

Materials and methods: A total of 79 patients suffered malignant jaundice in the period between January 1991 and December 1996. The three most frequent underlying tumours were gallbladder lesions, extra- and intrahepatic biliary tree neoplasms and tumours affecting Vater's ampulla. The incidence, diagnostic methods, treatment protocols and morbidity and mortality are evaluated.
Results: There were 47 females and 32 males (mean age 72·8 years, range 36–86). Routine investigations (ultrasound, computed tomography, endoscopic retrograde cholangio-pancreatography and transparietohepatic puncture) established the diagnosis in 69 per cent of cases. The diagnosis was established at laparotomy in 26 per cent of cases, and by histopathological study in 5 per cent. Extrahepatic biliary tract cholangiocarcinoma was the most common lesion (48·1 per cent), followed by gallbladder tumours (29·1 per cent) and neoplasms of Vater's ampulla (18·9 per cent); cholangio-carcinomas were the least frequent (3·9 per cent). A total of 44 patients were operated upon (55·6 per cent). There were 12 exploratory laparotomies. A total of 17 biliary stents were placed, and 8 external biliary bypasses were made via transparietohepatic puncture – 5 being definitive. There was no treatment in 14 cases (17·7 per cent). Immediate mortality was 34·1 per cent (n=27). There were no cholangitis episodes after placing autoexpanding stents.
Conclusion: Biliary tract tumours have a poor prognosis due to late diagnosis, rapid progression and near-lying tissue infiltration. Surgery does not tend to be curative; hence alternative, effective and scantly aggressive palliative measures should be evaluated.

Clinical, laboratory, operative differences in patients with malignant and benign biliary tract obstructions

N. Yuksek, N.A. Kama, T. Coskun, M. Doganay, E. Reis and E. Kesici *Ankara Numune Hospital, 4th Department of Surgery, Ankara, Turkey*

Aim: Biliary tract obstruction is an important and common clinical condition which usually demands surgical relief. The cause of obstruction determines outcome of patients. We conducted this study to clarify whether malignant and benign biliary tract obstructions have different effects on clinical, laboratory and operative factors.
Patients and methods: Thirty-six clinical, laboratory and operative parameters were analysed in 107 patients. There were 52 females and 55 males, with a mean age of 60 (ranged 24–87) years. The cause of obstruction was common bile duct stone (n=65) and malignancy (n=62). All patients in this study had surgical relief of jaundice. Those patients who did not undergo surgical biliary drainage were not included in this study (stone extraction by ERCP in 14 patients, laparotomy and/or biopsy in 7 patients with malignancy). The factors evaluated in these patients were: age, sex, weight loss, diabetus mellitus, previous surgery, history of smoking, concomitant medical disease, fever, Murphy's sign, clinical evidence of cholangitis, preoperative hospitalization time, preoperative ERCP, positive cultures, pre- and postoperative blood transfusions, preoperative oral intake, pre and postoperative total parenteral nutrition, operation time, postoperative complications, postoperative mortality, postoperative antibiotic usage, postoperative drainage time, pre and postoperative nasogastric tube drainage time, haematocrit, haemoglobulin, white blood count, platelet, blood urea nitrogen, creatinine, albumin, bilirubin, serum glutamic oxaloacetic (SGOT) and pyruvate (SGPT) transaminases and alkaline phosphatase. The chi-square test was used for statistical analysis.
Results: Those patients with malignant obstruction were found to have significantly high rates of weight loss, history of smoking, preoperative ERCP, high levels of SGOT, SGPT and bilirubin; pre- and postoperative blood transfusions, pre and postoperative total parenteral nutrition, postoperative complications and mortality statistically. Additionally those patients had longer operation, pre- and postoperative nasogastric tube drainage and postoperative drainage time. The rates of high creatinine levels and presence of Murphy's sign were found to be high in patients with benign obstruction.
Conclusion: Patients with malign biliary tract obstruction have high rates of postoperative morbidity and mortality compared with patients with benign obstruction. This may be due to severe disturbance of hepatocellular functions in these patients. Renal functions should be monitored carefully in patients with benign biliary tract obstruction.

Liver

Hepatic hydatid disease and therapeutic approach

C. Akaoğlu, A. Çökmez, E. Durak, A. Aslan, Ö. Berova and S. Deniz *İzmir Atatürk Training Hospital, 1st Surgery, M. Kernal Cad No 129 Ablok, Daire 8, 35040 Bornova, Izmire, Turkey*

Hepatic hydatid disease is one of the most important public health problems in our country. There are many different types of surgical approaches for hydatid disease of liver. We investigated 112 cases with hepatic hydatid disease treated surgically in our clinic for the last 10 years. Eighty-one patients were female (72·3 per cent) and 31 patients were male (27·7 per cent). Seventy-seven per cent of cases were admitted with the complaint of abdominal pain, 13 per cent with abdominal distention, 7 per cent with jaundice, 4·3 per cent with abdominal mass.

Eighteen patients (16·07 per cent) had recurrence. The most commonly used radiological method to demonstrate the lesion was ultrasonography (80 per cent). In 67·85 per cent of cases right lobe was involved and the lesion side was left lobe in 26·78 per cent of cases and 5·35 per cent of cases was bilateral.

In 112 patients 145 totally different cysts were found. Cysts were infected in 23 patients (20·50 per cent) and incorporated bile duct branches in 24 patients (21·42 per cent). The surgical approach was as shown below:

We preferred intraflection for 35 patients, omentoplasty for 33 patients, cystotomy + drainage for 26 patients, capitonage for 18 patients, total cystectomy for 13 patients, hepatectomy for 2 patients and aspiration for 1 case.

Most common complication was bile fistula. It was seen 14 per cent of patients. The discharging period varied between 9 and 147 days. Generally, complications occurred after cystotomy and drainage procedures. The most common preferred technique was intraflection. Different methods were used according to location of the lesion and condition of the patient. Of the available options, drainage was useful depending on the location of the cysts and in infected cases.

Comparison of different surgical methods performed for hepatic hydatid disease of the liver

M.L. Akin, C. Erenoglu, E. Uncu, C. Basekim and A. Batkin
GATA Haydarpasa Egitim Hastanesi, Genel Cerrahi Servisi, Kadikoy, 81327 Istanbul, Turkey

Aim: Hydatid disease of the liver is highly prevalent in Mediterranean countries, in which the population live mostly in rural areas. Although the taking out of the cyst itself is rather easy, management of cystic cavity is usually very difficult. The outcome of surgical methods used in management of cystic cavity with or without drainage in patients with hepatic hydatid disease was evaluated.

Materials and methods: Three hundred and forty consecutive patients who admitted to Department of General Surgery between 1988 and 1996 with hepatic hydatid disease were reviewed retrospectively. In the first group surgical methods without drainage such as cystectomy (n=11), capitonnage (n=55), omentoplasty (n=91) and capitonnage + omentoplasty (n=53), in the second group surgery with drainage such as external drainage (n=74), internal drainage (n=7), and combined methods (n=21) were applied. Role of symptoms and physical findings, types of surgical management, complication rate, hospitalization period, mortality and recurrence rates were evaluated.

Results: Complication rate, average hospitalization period, recurrence and mortality rates were 12·5 per cent, 9·5 days, 9·9 per cent and 0 per cent respectively in patients without drainage and 63·7 per cent, 26·5 days, 12·7 per cent and 0·9 per cent respectively in patients with drainage. The complication rate and hospitalization period in the group with drainage was significantly higher (P<0·001) than those of the group without drainage.

Conclusions: It is concluded that surgical treatment of hydatid disease of the liver without drainage decreases postoperative complication rate and average hospitalization period. Either drainage or non-drainage of cystic cavity has no effect on recurrence.

Pyogenic liver abscess in the elderly

J.A. Alvarez Pérez, R.F. Baldonedo Cernuda, J.J. González González, J.I. Jorge Barreiro and L. Sanz Alvarez *Dept. of Surgery, San Agustin & Central Hospitals, Univ. of Oviedo, Camino de Heros, 4, 33400 Avilés, Spain*

Aim: To present our experience in pyogenic liver abscess (PLA) in the elderly to try to analyse the clinical, diagnostic and therapeutic behaviour in this type of patient.

Materials and methods: From January 1985 to December 1995, 67 patients with PLA were treated in our units. These patients have been divided into two groups: under 61 years (32 cases) and over 60 years (35 cases). The mean age was 41·2±12·6 years and 73±6·7 years, respectively. Clinical features, associated diseases, laboratory test, imaging and microbiological findings, modality of treatment, associated surgery, morbidity and mortality were retrospectively assessed and compared in both groups. Statistical analysis was done by the χ^2 test for qualitative data and Student's t-test for quantitative data. Significance was taken at P<0·05.

Results: The pathogenesis of PLA by direct extension from an inflammatory process in adjacent structures was found most frequently in the elderly [7/32 (21·8 per cent) vs 17/35 (48·5 per cent), P=0·02]. In the same way, multiple abscesses appeared mainly in the elderly [5/32 (15·6 per cent) vs 13/35 (37·1 per cent), P=0·04]. Between the two groups there were no significant statistical difference referred to sex, symptoms and signs, APACHE II score, associated diseases, laboratory findings, size and location of the lesion, microbiologic data, method of treatment (antibiotics alone, percutaneous drainage, surgical drainage), associated surgery, morbidity and mortality.

Conclusions:

1. The pathogenic factor mainly in the elderly was an infection by direct spread.
2. There was no significant difference in the clinical and biological behaviour in the elderly with respect to younger patients.
3. Multiple abscesses were more frequently found in the elderly.
4. Neither in morbidity nor in mortality were there significant differences between the two groups of patients so age is not a risk factor in patients with this condition.

Hydatic disease of the liver: report of 304 cases

A.A. Balik, M. Başoğlu, D. Ören, Y. Polat, S.S. Atamanalp, M.N. Akçay and F. Çelebi *Atatürk University School of Medicine, Department of General Surgery, 25070 Yenişehir Erzurum, Turkey*

Aim: To investigate the management of the patients with hepatic hydatic disease retrospectively.

Patients and methods: Three hundred and four patients with hepatic hydatosis were operated between 1981 and 1996.

Results: Cysts were found in the right lobe in 238 patients, in the left lobe in 41 patients and bilateral in 25 patients. Forty-five patients had multiple hepatic and 18 had co-existing cysts in spleen, pancreas, adrenal gland, mesocolon, over, retroperitoneum, and abdominal wall. The diameters of the cysts were smaller than 5 cm in 13·5–10 cm in 106 and larger than 10 cm in 185 patients. There were infected cysts in 35 patients. The most frequent symptoms were upper abdominal pain and tenderness, fever, and less frequent jaundice and pruritis. Three patients were admitted with acute abdomen due to cyst perforation. Surgical procedures were partial cystectomy and drainage in 122, capitonage in 95, omentoplasty in 40, cyst excision in 22, segmentectomy in 10, and cystoenterostomy in 10 patients. Co-existent cysts were treated by splenectomy, oophorectomy and cyst excision. Ten patients with partial cystectomy and drainage developed chronic biliary fistula. No recurrence was seen in follow-up lasting from 3 months to 6 years. Povidone iodine, 20 per cent hypertonic saline solution and 95 per cent ethanol were used as scolosidal agents. Four patients died of unrelated causes.

Conclusion: Management of hydatic disease of the liver with capitonage, omentoplasty, cyst excision, segmentectomy, and cystoenterostomy are superior to tube drainage.

Liver resections for primary hepatocellular carcinoma

F. Berrevoet, S. De Laere, R. Troisi, M. Hautekeete*, H. Van Vlierberghe, U.J. Hesse, P. Pattyn and B. de Hemptinne *Dept of Surgery, *Dept. of Gasto-enterology, University Hospital, De Pintelaan 185, 9000 Gent, Belgium*

Hepatocellular carcinoma (HCC) is one of the most common malignancies worldwide with a poor prognosis and a high recurrence rate. Aim of this study was to review our results in 14 patients resected for HCC in the last 5 years.

Methods: From 1992 to 1997 14 patients underwent partial liver resection for primary HCC. There were 8 male and 6 female patients with a mean age of 68 years (range 30 to 73 years). Underlying cirrhosis was present in 9 of 14 patients. Tumour staging was assessed by ultrasonography. CT-scan and preoperative angiography. Three patients were stage I; five were II; 4 were III and 2 were IVa. HCC was single in 10 patients and multiple in 4 and the mean size was 5·8±4·2 cm. Types of resection were: right hepatectomy in 3 patients, left hepatectomy in 5, bisegmentectomy in 2, 1 segmentectomy, 2 subsegmentectomies and 1 atypical resection. Nine patients were pre-operatively treated by chemo-embolization (TAE). Synchronous metastasis was observed in 4 patients at time of surgery, and surgery was not curative in 2. Median follow-up was 24 months.

Results: Post-operative complications occurred in 3 patients: 2 cases of liver failure (14 per cent) and 1 pneumonia (7 per cent) with a total morbidity rate of 21 per cent. Recurrence in the liver was noticed in 4 patients with underlying liver cirrhosis (28 per cent). Mean time between surgery and HCC recurrence was 166 days (range 58 to 275 days). No peri-operative mortality was seen and overall mortality rate is 14 per cent. Two patients died within the first year because of local tumour recurrence. Overall patient survival and disease-free survival is 81 per cent and 74 per cent at 1 year respectively.

Conclusions: Despite a total low morbidity rate, HCC recurrence is still high especially in cirrhotic patients with a considerable risk of postoperative liver failure. The incidence of distant metastasis is rather low in our experience. We think that liver resection can be proposed as therapy of choice in selected patients with good liver function and localized HCC. Adequate pre-operative evaluation is mandatory to improve results.

Two stage hepatectomy in metastatic tumour invading right and middle hepatic veins

Z. Biejat, P. Białek and J.A. Polański *3rd Department of Surgery, Warsaw Medical School, Stepinska 19/25, 00-739 Warszawa, Poland*

Aim: Authors present the case of two stage operation in metastatic tumour from renal cell carcinoma located in segments 4 and 8 of the liver.

Case: Thirty-eight year old female patient was admitted to our department with 8 cm liver tumour 5 years after left nephrectomy. CT scans and power Doppler ultrasound have shown possible invasion of right and middle hepatic veins. With total liver volume of 1902 cm^3, the volume of segments 2 and 3 was insufficient to perform extended right hepatectomy with adequate tumour free margin.

Instead, right portal vein ligation and hepatoduodenal ligament lymphadenectomy was performed. She underwent this procedure on 7th February 1997. There was as extrahepatic malignancy. Postoperative course was complicated with massive right pleural effusion. In successive spiral CT scans performed 4 and 8 weeks after portal vein ligation total liver volume did not change significantly (1933 cm^3) but the volume of planned remnant liver segments 2 and 3 was estimated as insufficient.

We estimated this volume as satisfied and safe in 11 postoperative week. On 29th April the patient underwent right extended hepatectomy without any complications in postoperative period. Total volume of resected liver was 1120 cm^3 with approximately 750 cm^3 of remmant tissue. Twelve weeks after secondary operation segment 1+2+3 volume reached 1200 cm^3 and is stable up to last CT control performed on 19th December 1997. The patient has shown no signs of liver insufficiency or recurrence after both procedures.

Conclusion: In the well differentiating neoplasms there is time to wait long enough until the regeneration of unligated lobe will be satisfactory prior to hepatic resection.

Therapeutic strategy in the treatment of liver abscess: our experience

T. Ceragioli, A. Marioni, A. Lucchesi and C. De Nisco
Dipartimento di Chirurgia Generale, Università degli Studi di Pisa, Via Roma, 67, 56125 Pisa, Italy

The last 10 years we have treated 44 patients with liver abscess. Initially we have examined the general symptomatic conditions (APACHE), the ultrasonography lesion characteristics, and the presumed aetiology.

The first therapeutic approach consisted in specific antibiotic therapy associated with execution of percutaneous ultrasound-guided drainage. We have valued, successively, aetiology, drainage capacity and change of clinical symptoms examining biochemical and clinic parameters (fever, septic condition).

These parameters valued every 12 hours have been correlated with percutaneous drainage success. Only five patients needed another therapeutic approach (chemotherapy with intraportal catheter) or surgery by laparotomy. There were no deaths.

Correction of hypersplenism on liver cirrhosis patients

S.N. Chooklin and K.I. Boulanov* *Department of Surgery, Medical University, Pekerska 69, 290010 Lviv, Ukraine and *Institute of Clinical and Experimental Surgery, AMS Ukraine, Kiev, Ukraine*

Syndrome of the secondary hypersplenism is the serious complication of the portal hypertension on liver cirrhosis. One hundred and twenty-five patients with liver cirrhosis were studied. The moderate cytopenia in the peripheral blood was marked in 41 and significant – in 84 patients. Gastroesophageal varices were noted in 108 patients. 53 patients had a bleeding in anamnesis, the refractory ascites – in 50, the clinical evidences of the chronic portosystemic encephalopathy were present in 29 patients. Splenectomy was performed in 45 patients. The universal influence of splenectomy on the hypersplenism course was observed. However, several complications due to the immunocompetentive organ removing, sharply limit the indices to the splenectomy. At the present time, splenectomy is performed only in patients with the splenogenic liver cirrhosis (Child-Pugh A), where the autoaggressive function of the spleen was confirmed. The syndrome of hypersplenism did not often accompany this condition. At the last time, the embolization of the A. lienalis was applied as the alternative to the splenectomy. The embolization of the A. lienalis was performed in 84 patients (Child-Pugh B – 45, C – 39). The embolization of the trunk type and combined distal parenchymatous was used. In the nearest period after intervention the normalization of leukocytes quantity and increase to the subnormal value of the platelet number in the peripheral blood was observed. The number of erythrocytes and content of hemoglobin essentially did not change. The axis length of the lien reliable decreased, the clinical evidences of the secondary hypersplenism were absent. In the remote period in most patients the moderate asymptomatic cytopenia in the peripheral blood was noted, moreover the platelet number, on the whole, stayed stable, and a leukocytes quantity was decreased. The recurrence of the secondary hypersplenism was revealed in the various terms after operation in 10 patients. In 6 patients it was determined by the recanalization of A. lienalis after truncular proximal embolization, formation of collaterals to the spleen by the left gastrica (2), gastroduodenalis and gastricoepiploica (1) and pancreatic (1) branches. Recanalization was successfully performed in 8 cases.

Blunt liver trauma: retrospective analysis of 25 cases

R. Dalla Valle, G. Campanella and S. Contini *Istituto di Clinica Chirurgica Generale e dei Trapianti d'Organo, University of Parma, Via Gramsci 14, 43100 Parma, Italy*

Aim: Blunt liver trauma has increased strikingly in the last years, mainly in young patients. Although diagnostic tools and therapeutic solutions are improved, mortality is still high. We analyse retrospectively twenty-five patients with blunt liver trauma observed in our unit in the years 1990–96.
Materials and methods: US and abdominal CT scans were performed only in 17 hemodynamically stable patients. Eight patients were submitted immediately to surgery, with deep hypotension. Surgery was necessary in 14 of 25 patients (56 per cent) to control bleeding with suture, debridement or resection. Multiple organ lesions were present in 68 per cent.
Results: Sensibility of US and CT scan was respectively 88 per cent and 100 per cent. None of the 11 patients treated conservatively died but the overall mortality was 3/25 (12 per cent), all with associated lesions. Uncontrolled haemorrhage (one) and multiple organ failure (two) were the causes of death. These three patients were submitted to surgery being deeply hypotensive. The total surgical mortality was 21·4 per cent (3/14) but raised to 37·5 per cent (3/8) considering only patients operated in a shock state. Postoperative morbidity was 21 per cent and in one patient a liver transplant was necessary for a severe postoperative liver failure.
Conclusions: A conservative approach is possible if the patient is haemodynamically stable, mainly for the reliability of US and CT scan allowing accurate monitoring: about half of the patients could be treated in this way. Associated lesions and deep hypotension before surgery carry a poor prognosis, with a death rate of almost 40 per cent. When it was possible to stabilize the vital signs before surgery, mortality was nil.

Is subtotal cystopericystectomy a safe procedure to treat hydatidic cysts?

M. Penabad González, A. Serrano Minguillón, M. Bañeres López, F.J. López Rebollo, J. Lizán Lagos, J.J. Bienzobas Resa and J.M. Gil Del Val *Obispo Polanco General Hospital, av. Ruiz Jarabos 5, 44002 Teruel, Spain*

Hepatic infestation of *E. granulosus* is a disease extended through the whole world. Nowadays the only efficient treatment is surgery. All the proposed techniques can be divided in conservative or radical procedures.
Objective: To analyse the morbidity and mortality of subtotal cystopericystectomy (SCP).
Material and methods: In the last 10 years 69 patients with 81 hydatidic cysts have been operated on. Mean age 45 years (range 16–82). Thirty-two cysts had a clear, sterile content. Forty contained bile and 9 were infected. In all cases punction-aspiration of the cyst was performed, injection of hypertonic saline solution (20 per cent) followed by resection of the emergent adventicia, silk suture of the biliar communications and external drainage (12 latex, 57 silicone).

Cholangiography was performed in 35 patients, being necessary a choledocotomy in 7 cases. Cholecystectomy was done in 19 cases. All the patients were treated with antibiotics for a period of 5 days minimum.
Results: Mortality 1/69 due to traumatic rupture of the cyst in a 87 year old patient. Morbidity: 3 biliary fistulas over 7 days resolved after endoscopic papillotomy, 7 intrabdominal abscesses in patients with latex drainages. In 6 times the abscess were treated by CT guided punction. Only 1 patient required open surgery to treat the abscess. Culture results were: 4 *Streptococcus*, 3 *Staphilococcus aureus*. Eleven patients had basal pneumonia. Mean stay 7·2 days (5–21).
Conclusions:
1. SCP is an easy and safe procedure to treat hepatic hydatidic cysts.
2. Close system drainage and antibiotics are necessary to avoid infection of the residual cavity.

Partial pericystectomy vs capitonage in large hepatic echinococcus cysts

A. Krasniqi, D. Limani, R. Jashari, M. Maxhuni and R. Binishi *Medical Faculty, University of Prishtina, Kosova*

Aim: The aim of this study was to present our experience in the surgical treatment of large hepatic echinococcus cysts. As large cysts were considered those which involved more than three liver segments and had communications with biliary tract.
Patients and methods: In a 10 year period (1981–1990) 130 patients with hydatid cysts surgically were treated; 64 (49·2 per cent) of them had large cysts. Cyst daughters in common bile duct and choledochus were found in 22 (34·5 per cent) of patients with large ones. Female/male ratio was 38 (50·6 per cent) to 26 (47·2 per cent).

Three methods of treatment were used: 1) cystectomy followed by capitonage of cavity (12 patients), 2) cystectomy with total pericystectomy and omentoplication (30 patients), and 3) cystectomy followed by partial pericystectomy, cholecystectomy, exploratory choledochotomy (removal of eventually cysts daughters), T-drainage with intraoperative cholangiography, and omentoplication (22 patients). Saline solution was injected through T tube to identify biliary openings on the cavity surface, and after that smaller openings were carefully sutured, whereas the eroded larger ducts were continually sutured using 5·0 polyglactin 910 (Vicryl).
Results: The perioperative mortality rate was zero. After the analyses and five years ultrasonography follow up of each patient we recorded 13 postoperational biliocutaneal fistulas, one retention of cyst daughter in common bile duct and two recidivation of hepatic cysts. In the groups of patients treated with methods 2 and 3 it was no recidivation nor retention of cysts in biliary tract. The patients treated with second method had longer hospital stay (22·6 days in average).
Conclusions: These results suggest that in the treatment of large hepatic echinococcus cysts (where total pericystectomy is infeasible) the second method had better outcome and it provides better possibilities for early postoperative follow up.

Indications and results of the oesophageal stapled transsection for bleeding varices

S. Malinger, T. Kościński and M. Drews *III Department of Surgery, University School of Medicine, Poznań, Poland*

The first choice treatment for haemorrhage from ruptured oesophageal varices is endoscopic injection sclerotherapy. Surgical treatment however may be indicated for recurrent bleeding or inefficient variceal obliteration. This study was performed to assess the efficiency of stapler transsection of the oesophagus to stem the haemorrhage.
Patients and methods: Between 1988 and 1996, 28 patients (aged from 32 to 70 years) have been operated on. Hepatic cirrhosis was the main cause of variceal appearing. Child's hepatic failure evaluation showed stage A in 12 patients and stage B in 16 patients. Emergency indications for the surgical treatment were present in 5 patients, selective indications – in 23 patients.
The operative technique: Consisted of introduction of a stapler device (ILS) by a gastrotomy to the subdiaphragmatical part of the oesophagus. The band was tied around the oesophageal wall upon opened stapler working head. Firing of the device formed a double layer end-to-end anastomosis transsecting and ligating the submucosal varices. When the vagal trunks could not be saved a pyloromytomy was performed.
Results: There were 4 important rebleedings and 2 anastomotic leaks postoperatively. Five patients died, 3 of them were operated on in emergency for massive haemorrhage. After one year 11 variceal relapses were observed.
Conclusions:
1. The surgical treatment should be reserved only for inefficient endoscopic control of life-threatening haemorrhage.
2. The great advantage of stapler transsection of the oesophagus is relative simplicity of use and minor risk of complications.
3. One about 50 per cent of the patients treated by this method remain free of varices one year after the operation.

Technique of interstitial laser therapy (ILP) in our experience

Gy. Orgován, F. Tauzin, G.C. Kovács, B. Bakity and
Z. Záborszky *Surgical Department, Central Military Hospital, Róbert Károly krt. 44, Budapest H-1134, Hungary*

Locally destroying of colorectal metastases of the liver is an accepted method by ILP. The most promising ILP results are in the treatment of liver metastases, if they are smaller than 3 cm.

The main problem with this method is to monitor tissue changes in real time, and ultrasonography was found to be a little help in this respect. The thermal effects are detectable by high-speed magnetic resonance imaging (MRI) sequences. It can be used to monitor laser-induced tissue changes during therapy, but it is very expensive.

CT, ultrasound or laparoscopic techniques were used to localize the tumours. 19G needles were inserted into the tumour, and through the needle was passed a thin cylindrical diffuser optical fibre. The tumour was heated using low power laser light (2 W) for different time from a Nd:YAG or diode laser, dependant on the tumour size.

New method in human application is thermography to control the thermal effect in real time mode.

With optimal technique, ILP may in the future become a practical, minimally invasive treatment option for patients with colorectal metastases of the liver.

Hepatic resection for benign and malignant liver tumours: experience with 121 consecutive patients

M. Pardela, M. Wyleżoł, W.K. Karcz, M. Lemieszewski and
M. Dróżdż *2nd Departmment of General and Vascular Surgery, Silesian University School of Medicine, ul. M. Curie-Skłodowskiej 10, 41-800 Zabrze, Poland*

We performed retrospective analysis of 121 consecutive patients underwent partial liver resection in our department between 1985 and 1997. There were 79 (65·3 per cent) patients with primary tumours: 44 (55·7 per cent) benign and 35 (44·3 per cent) malignant. Metastatic tumours were diagnosed in the remaining 42 (34·7 per cent) cases: 9 (21·4 per cent) synchronic with primary tumour and in 33 (78·6 per cent) cases metachronic. Following resections were performed: segmentectomy in 29 (23·9 per cent) cases, bisegmentectomy in 34 (28·1 per cent), trisegmentectomy in 12 (9·9 per cent), hemihepatectomy in 14 (11·6 per cent) and non-anatomic resections in 32 (26·5 per cent) cases. The benign group consisted of: hemangiomas 19 (43·2 per cent), inflammatory tumours 14 (31·8 per cent), cysts 11 (25 per cent). There were no deaths in postoperative period in patients with benign tumours. We observed: pneumonia in 6 (13·64 per cent), subphrenic abscess in 3 (6·81 per cent), wound infection in 3 (6·81 per cent), biliary fistula in 2 (4·54 per cent) cases. The main reason of metastases was colorectal cancer 71·43 per cent ($n=30$) then gastric cancer 14·29 per cent ($n=6$), biliary duct cancer 7·14 per cent ($n=3$), ovarian cancer 4·76 per cent ($n=2$), idiopatic 2·38 per cent ($n=1$). The mortality rate in the group of 77 patients with malignancy was 10·4 per cent (8 patients). Postoperative complications rates were as follows: pneumonia 14·28 per cent ($n=11$), wound infections 9·09 per cent ($n=9$), biliary fistula 6·49 per cent ($n = 5$), subphrenic abscess 6·49 per cent ($n=5$), acute liver insufficiency 5·19 per cent ($n=4$). Hepatic resection can be a routine procedure in all cases of liver tumours. Intensive care is needed mostly in patients with malignancy.

Complex treatment for liver metastases of colorectal cancer

A. Petri, I. Zöllei and Á. Balogh *Department of Surgery, Albert Szent-Györgyi Medical University, 6701 Szeged, P.O.B. 464, Hungary*

Aim: Colorectal cancer is the second frequent cause of death – behind the liver cirrhosis – among the gastrointestinal disorders in Hungary. About 25 per cent of the patients have liver metastases at the time of detection of their colorectal tumour and about at 50 per cent of them have det liver metastases during the course of their disease. Whereas about patients died every year as a consequence of colorectal cancer the nu of those whose liver metastases have not been treated neither with su nor with chemotherapy is very high. We accomplished a retrospe analysis among patients with liver metastases of colorectal cancer h been treated with different methods.

Materials and methods: From January 1982 to December 199 patients had been treated for metastatic colorectal carcinoma. There 43 men and 52 women, the mean age being 55·69 years, ranged 25–79 years. Primary colorectal cancers had all been resected. 85 pa could be classified at the time of the primary resection as Duke's in 10 cases the stage was unknown. We performed in 37 cases a maj 11 cases a minor liver resection, in 11 cases an arteria hepatica can tion, in 7 other cases a vena portae cannula have been simultane implanted for cytostatic therapy. Portal triad occlusion was used in the cases. If the tumour because of its extent or multiplicity could n removed we implanted in 31 patients an arteria hepatica, in 6 patie vena umbilicalis cannula for cytostatic therapy. In 8 cases could on made on exploration. The patients received in the postoperative peri FU and Doxorubicin for cytostatic therapy in every six weeks.

Results: There were no intraoperative deaths in this series. Postope mortality rate was 3·16 per cent. The mean survival was after majo minor surgery 41·4 ($P<0{\cdot}005$) and 25·69 ($P=0{\cdot}0715$) months, wh after implantation arteria hepatica and vena umbilicalis cannula 12·84 and 7·2 month. The mean survival after exploration was onl month.

Conclusions: We have the opinion, that only an aggressive surgery use of adjuvant chemotherapy should prolong the survival of patients ing liver metastasis of colorectal cancer.

Hepatic hydatic cysts: managment with percutaneous draina

Y. Polat, A.A. Balik, D. Ören, M. Başoğlu, S.S. Atamanalp, M.N. Akçay and I. Yildirgan *Atatürk University School of Medicine, Department of General Surgery, 25070 Yenişehir Erzurum, Turkey*

Aim: To investigate the results of percutaneous drainage of hydatid of the liver prospectively.

Patients and methods: One hundred and one patients, with 120 c were treated with percutaneous drainage between October 1994 December 1997.

Results: Of the cysts, 89 were in the right lobe and 31 were in the lobe. Thirty-one patients had been operated for hydatic disease previo All cysts had anechoic or hypoechoic unilocular sonographic appear The mean dimension of the cysts was 7·5±2·9 cm (range 3–10·4 cm). patients received oral 10 mg/kg albendasole perioperatively. After as tion of the cysts under sonographic guidance, they were irrigated wit per cent ethanol. The amount of cyst fluid aspirated and irrigation sol used were 220±75 cc and 175±42 cc, respectively. Four patients devel febrile fever and 3 patients urticaria. The mean hospital stay was 2·1 (range 1–4) days. Patients were followed up 6–39 months. Serial s graphic examinations revealed heterogen echos in cyst cavity (pse tumour). Maximal cyst diameter decreased from 7·5±2·9 cm to 3·2±1· ($P<0{\cdot}001$).

Conclusion: Management of most hydatid cysts of the liver is pos with combination drug therapy and percutaneous drainage.

Our surgical experiences about the hepatic metastases of colorectal tumours

I. Takács, J. Bóni, A. Vágvölgyi, Cs. András and P. Sápy *2n Department of Surgery and *3rd Department of Internal Medicine, University Medical School of Debrecen, Hungary, Móricz Zigsmond, krt. 22, Debrecen 4004, Hungary*

Aim: Authors evaluate the results of the surgical treatment in case of 24 patients underwent liver resection because of hepatic metastase colorectal tumours.

Patients and methods: Between 1992 and 1997 authors performed liver resection on 24 patients because of the metastasis of colorectal tumour (16 male, 8 female, mean age: 57·6 (32–76). Simultaneous resection of the colon with simultaneous liver operation were performed in 11 cases. In 13 cases hepatic resections were performed at a different time on average 5·9 (1–12) months after the resection of the colorectal tumour. Hepatic metastasis was known at time of the primary operation in 4 cases of them. The surgical method were the following: 6 atypical resections, 7 resections of one hepatic segment, 5 resections of two hepatic segments, 4 hemihepatectomies, 2 lobectomies. In 7 cases multiplex metastasectomy was performed. The average size of the removed tumour was 5·8 (2–18) cm.
Results: There were no mortality in the early postoperative period. Complications were the following: fever (2 patients), transitional elevation of the hepatic enzymes (2 patients), pleuropneumonia (2 patients), TIA (1 patient). There were no surgical complications.
Conclusions: According to our results authors think that the removal of hepatic metastases simultaneously with the removal of the colorectal tumours can be chosen for the elective surgery in cases when the general state of patient allows it. In the case of elder age, other accompanying diseases removing the colon tumour and its liver metastasis is preferable at a different time.

Ultrasound guided aspiration biopsy of focal liver lesions

Z. Tarján, T. Winternitz*, B. Járay**, G. Tóth, H. Galgóczy and Z. Vígváry *Dept. of Radiology, *1st Dept. of Surgery, **1st Dept. of Pathology, Semmelweis Medical University, Ulloi ut 78/a, 1082 Budapest, Hungary*

Aim: To evalue the diagnostic value of Ultrasound Guided Percutaneous Fine Needle Biopsy (US-FNAB) in diagnosing focal liver lesions.
Materials and methods: During the last 6 years 552 US-FNABs were performed in patients with suspected neoplastic involvement of the liver with 22-gauge Chiba needles, mostly with 'free hand' technique.
Results: Sufficient material for cytological analysis was obtained in 93 per cent of the cases. The biopsies confirmed malignancy in 39·3 per cent, including 14 per cent primary hepatocellular carcinoma. Nine per cent of the cases was suspected of malignancy and in 29·7 per cent benign lesions were diagnosed. Two hundred and thirty-three cases were confirmed histologically and with other follow up methods. The sensitivity rate was 91 per cent, the specificity 100 per cent. There was not any false positive diagnosis and no noteworthy complications were observed.
Conclusion: US-FNAB is a highly reliable, safe, inexpensive diagnostic procedure. Based on our experiences we advise US-FNAB as a routine, first level tool for the diagnosis of focal liver diseases.

Current strategy in the management of hepatic injury

K. Van Renterghem, C. Remue, U.J. Hesse, P. Pattyn and B. de Hemptinne *Dept. of Surgery, University Hospital Gent, De Pintelaan 185, 9000 Gent, Belgium*

The presence or suspicion of hepatic injury has traditionally been an indication for surgical exploration. On the other hand, non-operative management is nowadays considered the treatment modality of choice in over 50 per cent of patients with blunt hepatic injuries. The following report analyses retrospectively our experience over the past 5 years.
Patients and methods: The charts of all patients with liver injuries admitted to our hospital during the past 5 years were reviewed. Information collected includes age, sex, mechanism of injury, associated injuries, treatment, complications and outcome. Diagnosis was suspected or proven by either peritoneal lavage or CAT-scan.
Results: Forty patients (m/f: 30/10), with a mean age of 32·7 years, were treated for hepatic injury. Traffic accident was the mechanism of injury in 33 patients, fall of a height in 3, blunt injury in 3 and penetrating trauma in 1 patient. Diagnosis was made by peritoneal lavage in 14 patients, by CAT-scan in 24 and on clinical examination in 2. Isolated liver injury was present in only 4 patients. Twenty-two patients underwent laparotomy (12 simple haemostasis, 6 packing, 3 partial hepatectomy, 1 total hepatectomy awaiting transplantation). In 13 of the 22 operated patients, diagnosis was suspected by peritoneal lavage only. Nine of these patients had associated intra-abdominal lesions that made laparotomy mandatory (6 spleen, 1 kidney, 2 intestinal). Two patients developed a biliary leak, one was treated by endoscopic stenting. Five patients died (22·7 per cent). Mean ICU stay was 12 days. Eighteen patients were treated conservatively. Diagnosis was confirmed by CAT-scan in all of these patients. Four patients had associated intra-abdominal lesions (2 spleen, 2 kidney). One patient developed a haemangioma. No patient died. Mean ICU stay was seven days.
Conclusion: In this series surgery remains the cornerstone in therapy of blunt-abdominal trauma with acceptable morbidity and mortality. Packing is the surgical procedure of choice, while resection and total hepatectomy awaiting transplantation is associated with high mortality. The additional endoscopic stenting of biliary fistula facilitates the postoperative course.

Surgical treatment of the echinococcus cyst in the liver (1991–1997)

G. Varga, I. Takács and P. Sápy *2nd Department of Surgery, University Medical School of Debrecen, Móricz Zs. krt. 22, 4004 Debrecen, Hungary*

Aim: The aim of this study was to obtain more data about the surgical treatment of echinococcus cysts in the liver. The commonly used techniques are pericystectomy, enucleation, anatomical or atypical resection.
Material and methods: Thirty patients (19 female and 11 male) with liver echinococcus cyst underwent surgical operation between January 1991 and December 1997. Solitaer cyst was removed in 20 cases, duplex cyst in 6 cases. Echinococcus cyst of the liver was resected by a thoracolaparotomy following cystectomy of the left liver lobe of the lung in one patient. The average size of the cysts was 10 cm (5–15 cm). Marsupialization was chosen in 1 case with secondary abscess formation in the cyst, six years ago. We performed single segment resection in 8 cases, double segment resection in 5 cases, three segment were removed in 3 cases. Atypical resection was achieved in 2 cases, pericystectomy in 5 cases, and enucleation in 5 cases. Hemihepatectomy was necessary in 1 case.
Results: One patient died in cardiac failure. Seroma developed in one case. All patients were free of symptoms during their follow-up.
Conclusion: Enucleation or anatomical segment resection of the liver proved to be the best method. We obtained very good experiences with application of the ultrasound dissector.

Benign hepatic tumours: analysis of 19 cases

L. Vlad*, M. Grigorescu**, S. Cotul***, P. Szima*, R. Vasilescu* and R. Henegar **Clinic of Surgery No. 3, str. Iaşilor, 29, 3400 Cluj-Napoca, Romania, **Clinic of Internal Medicine No. 3, and ***Department of Nuclear Medicine, University of Medicine, Cluj, Romania*

Among 93 patients operated in the period 1st January 1992–30th November 1997 for primary liver tumours, we found 19 benign hepatic tumours (48 per cent): 15 hemangiomas, 1 adenoma, 2 hamartoma and 1 focal nodular hyperplasia. Hepatic hemangioma was the most frequent in our series (16 per cent), in 4 cases being located to one segment, in 5 cases extended to 3 segments, 1 case to right lobe and in 5 cases to the left lobe. The preoperative diagnosis was based on the hyperechoic pattern at the ultrasonography and the intense peripheral enhancement after the administration of contrast agent bolus, as well on HPI (hepatic perfusion index) by means of hepatic scintigraphy. The clinical examination found a palpable hepatic mass only in 5 cases – giant hemangioma occurred in 1 case (in this case the surgical exploration demonstrated the definitive diagnosis). The laparotomy was done in all cases: in 10 cases we performed only the exploration and biopsy, in 3 cases left lobectomy, in 1 case left hepatectomy and in 1 case the resection of the quadrant lobe. All patients with hemangioma had a good postoperative outcome, without complications.

One patient presented hepatic adenoma. In this case because the intratumoural bleeding, the preoperative diagnosis suggested cavernous hemangioma. The operation consisted in segmentectomy of the segment IV, the final diagnosis has been demonstrated by the histologic examination of the resected parenchyma.

The hepatic hamartoma was found in two cases, both being operated (hepatic excision – 1 case and left lobectomy – 1 case) and the diagnosis was made after the histologic examination of the resected specimen. One patient with focal nodular hyperplasia was cured by segmentectomy (segment VI) and the postoperative histologic examination pointed the type of the tumour.

In conclusion the heterogeneous appearance of these tumours require surgical exploration and biopsy to avoid the confusion with various malignant hepatic lesions. Finally we discuss the various imaging patterns of the benign hepatic tumours.

Emergency hemihepatectomy and colon resection for septic shock due to diverticultis and hepatic abscess

M. Wunsch, A. Wunsch and G. Otto *Department of Transplantation Surgery, University of Mainz, Langenbeckstr. 1, D-55101 Mainz, Germany*

A 49-year-old woman was referred to us with the diagnosis of multiple abscesses involving the right liver lobe and severe septicaemia. Intravenous antibiotics and operative insertion of a drain tube into the right liver had not prevented rapid deterioration to a critical condition. Upon arrival, the patient was intubated and depended on high doses of catecholamines to maintain adequate blood pressure readings. Emergency laparotomy revealed diverticulitis of the sigmoid colon with perforation as the cause of the disease. A right side hemihepatectomy and resection of the diseased colon segment were performed with an end colostomy and a Hartmann pouch. The patient could be weaned from the ventilator on the 18th postoperative day. The course was complicated by infected pleural effusions and partial secondary healing of the skin incision.

Conclusion: In this case, emergency hemihepatectomy favourably influenced the course of a septic shock syndrome due to multiple abscess formation in the right liver lobe and a perforation in the sigmoid colon.

Stomach

Marginal ulcer: a series of 40 cases

N. Akyürek, A. Bedirli, O. Yüksel, M. Kerek and Y. Arıtaş *Erciyes University Medical Faculty, General Surgery, Kayseri, Turkey*

Aim: Marginal ulcers are among the most important problems complicating ulcer surgery. Nowadays, except for the complications, arguments still persist about the treatment of marginal ulcers.
Materials and method: In this article, 40 cases with marginal ulcers were examined retrospectively. The type of initial operation, the initial symptoms, the tools to establish the diagnosis, the localization of the ulcer and the treatment approaches were reviewed.
Results: Thirty-one patients (77·5 per cent) were male and 9 (22·5 per cent) were female, all having a mean age of 46·8 years (range: 20–74 years). The initial operations were gastrojejunostomy in 23, gastric resection procedure in 12 and pyloroplasty and vagotomy in 5 of the patients. Twenty patients had come with perforation, 10 patients with bleeding and the remaining 10 patients with gastric stasis. Marginal ulcer was located on the line of anastomosis in 13 patients and distal to the anastomosis in 3 patients. Four patients were urgently operated for haemorrhagic shock secondary to upper gastrointestinal bleeding. The remaining 20 patients had emergency operations for acute abdomen. The mean latency period for the appearance of marginal ulcers was 9·6 years (range: 8 months–25 years). Among the 16 patients with incomplete vagotomy, 2 underwent only complete vagotomy procedure, and among the remaining 14 patients, 7 had primary repair procedure, 4 had transfix sutures, the remaining 3 patients had antrectomy in addition to complete vagotomy procedure.
Conclusion: As a result, incomplete vagotomy might be an important factor for the development of marginal ulcers. Of the treatment options, we are in favour of resection procedures.

Cancer of the stomach in the clinic of surgery at the present time and 25 years ago

M. Gryszkiewicz, J. Wasiak, R. Markert and D. Sokołowski
Clinic of General Surgery and Transplantology, Topcińskiego 22, 90-153 Łódź, Poland

Despite marked advancement in the development of diagnostic techniques, gastric cancer is still diagnosed too late. The aim of the study was comparison of patients operated upon in the Clinic of Surgery at present (in the years 1992–97) and 25 years ago (in the years 1965–70). The number of patients operated for gastric cancer in these two periods of time was similar (100 and 97 patients, respectively), with only a slight increase in their mean age. There was more than a twofold decrease in the number of preoperative misdiagnoses (18 per cent vs 7 per cent) and in the number of patients who underwent only explorative laparotomy (35 vs 14 persons). The number of patients fit for resection procedures rose from 56 per cent to 69 per cent. A threefold rise in the number of radical gastric resections was noted, and this resulted from the widely used stapling techniques.
Conclusions:
1. The above comparison has shown the following:
   - a similar number of operated patients,
   - a persistent high percentage of inoperable cases of gastric cancer and of palliative operations,
   - a threefold increase in the number of performed gastrectomies.
2. The patients present themselves to the surgeon too late despite the development of newly devised diagnostic techniques.

A decline of scheduled gastric surgery?

M. Gryszkiewicz, R. Markert, J. Wasiak and A. Waniek *Clinic of General Surgery and Transplantology, Topcińskiego 22, 90-153 Łódź, Poland*

Introduction in the last decade of new antiulcerous drugs has brought about a turn in the treatment of chronic peptic ulcer disease which at present is being handed over to the care of the internists. There is an ever increasing number of patients with complications of chronic peptic ulcer.

In the years 1967–1974 – 373 patients (4·9 per cent of all operations) were operated for chronic peptic ulcer. Scheduled operations were performed in 61 per cent and emergency operations in 39 per cent. Median age of the operated patients was 45·5 years, 22 per cent were under 35 years of age, and 4·5 per cent – over 70 years of age.

In the years 1989–1996 – 259 patients were operated for gastric and duodenal ulcer (3·2 per cent of all operations). Sixty-four per cent of them were operated for haemorrhage and perforation, and 36 per cent – because of ineffective conservative therapy. Median age of the operated patients was 55·5 years, 13 per cent of them were under 35 years of age, and 21 per cent – over 70 years of age.
Conclusions:
1. A decrease in the percentage of patients operated for chronic peptic ulcer disease.
2. An almost fivefold increase in the percentage of operated patients over 70 years of age.
3. An almost twofold decline of scheduled operations.

Jejunal pouch after total gastrectomy

C. Guerrera, A. Graziano, M.G. Minardi and R. Pistorio *Dip. di Chirurgia Universita' di Catania, Istituto di Chirurgia, Catania, Italy*

The agastric syndrome after total gastrectomy clinically determinates denutrition and ponderal waste which are always present in acute way in the postoperatory and then in chronic.

These depend on malabsorption and/or quick transit (loss of protein, creatorrhoea, steatorrhoea) or by other (AA) by a drastic reduction of the caloric intake. In absence of neoplastic relapse, the caloric intake can depend by low alimentary capacity with early repletion, dysphagia, oesophagitis, and by alimentary fears.

AA describe the surgical technique performed in six selected patients that had a Roux-en-Y esophagojejunostomy with Hunt-Rodino Pouch and the postoperative results by evaluation nutritional status.

The use of mechanical staplers is very useful. The pouch must not be longer than 16–18 cm to avoid too big dilatation with food residue. However the anastomotic tract from oesophagus to the end of loop must be not less than 40 cm.

Patients were studied by nutritional habits (number of meals, and postprandial disturbances), and by clinical, laboratory, instrumental follow-up: such as protein loss, Vit B12 hoematic concentration and intestinal absorption (Shilling test), xilosuria 24/h, steatorrhoea, glucose tolerance, endoscopy, rx-graphic transit, and emptying time of Pouch by sequential scintigraphy with Tc99.
Results: a) Chronic malabsorption persist in 100 per cent with loss of 350–400 Kcal/die with stool. b) Normal body weight occurred only in four patients (waste inf. 10 per cent). c) Very good protection against biliary reflux, dumping and postprandial disturbances. d) Good reservoir function with gradual food release, the emptying time is like a normal stomach (70–80') if not occurs a bigger dilatation of Pouch (one case).
Conclusions: The increased nutritional capacity does not always mean a greater food intake (maximum 2000–2200 Kal/day), no more a satisfactory physical recovery. The method only satisfies partially the aims however it is a safety intervention recommended only for patients having long life expectation.

Application of the Japanese approach to gastric cancer treatment: does it improve our results?

A. Gutiérrez, A. López, M. Diez, A. Martín, J.M. Mugüerza, J. Escribano and J. Granell *Hospital Universitario Príncipe de Asturias, Universidad de Alcalá de Henares, Servicio de Cirugía General, Ctra. Alcalá-Meco s/n., 28805 Madrid, Spain*

Aim: The differences between survival rates in the Western and Eastern countries for gastric cancer have been explained often because a different biological behaviour. Other reasons have also been argued: a better staging system, and a more systematic and aggressive surgical technique, in contrast to a rather pessimistic and nihilistic attitude with this tumour, common among many western well trained surgeons. The aim of this study is to present our results, after applying the Japanese approach to gastric cancer in our hospital.

Methods: From March 1988 to December 1997, 190 gastric cancer patients have been operated in our department. Classification, staging and treatment were performed according to the rules of the Japanese Society for Research of Gastric Cancer (JRSGC) Kaplan–Meier method was applied to survival analysis.

Results: The antrum was the most frequent tumoral location 44 per cent (85/190). Early gastric cancer was diagnosed in 25 cases (13 2 per cent). Patients distribution per stages was· I· 29 (15 per cent), II. 13 (6 per cent), III: 61 (32 per cent) and IV 87 (45 per cent) Elective surgery was performed in 88 per cent (168) of the total number of cases. Total gastrectomy was performed in 88 cases (46 per cent) and subtotal resection in 79 patients (41 per cent). D1 lymphadenectomy was associated in 66 cases, D2 in 86 and D3 in 12. The procedure was defined as absolute curative in 72 cases (38 per cent), relative curative in 35 (18 per cent) and non-curative in 83 (44 per cent). Overall survival after a mean follow-up period of 57 months is 41 per cent After curative surgery the cumulative survival has been 62 per cent, and 5 per cent for non-curative procedures

Conclusion: The Japanese approach to gastric cancer in our experience allows a better staging and prognostic definition of every case, based in clear, objective and realistic criteria

Has lymph node dissection for gastric cancer surgery a therapeutic significance?

A. Gutiérrez, A. López, M. Diez, A. Martín, T. Ratia,
J. Escribano and J. Granell *Hospital Universitario Príncipe de Asturias, Universidad de Alcalá de Henares, Servicio de Cirugía General, Ctra. Alcalá-Meco s/n., 28805 Madrid, Spain*

Aim: Although for Japanese authors, lymph node dissection has a definite therapeutic value, it hasn't been until 1994 that western publications have appeared which show and improved survival with extensive dissections vs standard Nevertheless this is still a matter of controversy. The aim of this study is to evaluate in our patients, studied according to the criteria of the Japanese Society for the Research in Gastric Cancer, whether an extended lymph node dissection (D_2/D_3) is associated with an improved survival, or only has contributed to improve staging and a more precise definition of prognosis

Patients and methods: From March 1988 to December 1996, 190 patients have been operated on for gastric adenocarcinoma in our Department. Clinicopathological variables as well as the definitions of surgery were evaluated according with the criteria of the Japanese Research Society for the Study of Gastric Cancer (JSRGC)

Results: The resection rate in our series is 88 per cent (168), with 76 per cent (145) presenting with advanced disease (stages III–IV). Eighty-eight total and 79 subtotal gastrectomies were performed. Lymph node dissection was: D_0· in 4, D_1· in 66, D_2. in 86, and D_3: in 12 patients respectively Postoperative lymph node involvement for resected tumours was. n0 63, n1· 45, n2. 37, n3. 23 patients. Surgery was defined as absolutely curative in 72 (37 per cent), relatively curative in 35 (18 per cent) and no curative in 83 (43 per cent). For patients without lymph node involvement, overall probability of survival with D_1 dissection was 75 per cent vs 65 per cent for D_2–D_3 (no significative). For patients with n1 lymph node involvement, survival with D_1 was 0 per cent, being 63 per cent for D_2–D_3 (P<0·01). With n2 involvement and D_2–D_3, overall survival was 22 per cent

Conclusions: When there is no lymph node involvement, a more extensive lymph node dissection adds nothing in terms of survival, but when there is lymph node involvement, patients' survival improves with a more extensive dissection

Different growth pattern in early gastric cancer-cause of different prognosis?

N. Hennes, M. Aleksic, J. Lützeler and B. Ulrich *Dept. of Surgery, Gerresheim Hospital, Gräulinger Str. 120, 40625 Dusseldorf, Germany*

Aim: In 1983 Kodama in Japan described different growth pattern in early gastric cancer (penetrating type A and B) and their influence on the prognosis. In Europe, this classification is not applied regularly. Working up our patients suffering from early gastric cancer (EGC), we tried to find out about the influence of the different growth pattern on long-term survival.

Material and methods: From October 1987 to March 1997, 43 patients suffering from early gastric cancer were operated in our department Twenty-two of these were found to have submucosa-type EGC which presented in 13 cases as the more aggressive PEN A type, and in nine cases as the more benign PEN B type.

Results: The histological investigation of the specimen showed positive lymph nodes in two patients of the PEN A group (1×N1, 1×N2) and in one patient of PEN B (N1).

We could follow-up our patients between 6 and 121 months (mean. 51 months). One patient of the PEN A group died in the 28th postoperative month tumour-related, another in the 76th postoperative month from myocardial infarction. One patient of the PEN B group died in the 41st postoperative month from his coronary heart disease

Conclusion: Within our small number of patients we could not prove that the PEN A type is more aggressive. Because of the impressing pathomorphological differences, we consider it necessary to obtain the data of more patients and to follow them up for a longer period of time

Advanced gastric cancer: an emergency hospital experience

G. Ionescu, S. Pâun, Ş. Jianu, B. Gaspar, I. Licà, G. Jinescu and R. Dop *Department of Surgery, Clinical Emergency Hospital, Calea Floreasca 8, 71406 Bucharest, Romania*

The study tries to establish a clinical and therapeutical attitude for advanced and complicated gastric cancer in an emergency hospital condition taking into consideration the last five years personal experience

Two hundred and forty-eight patients with minimum IIIA Stage disease (International TNBM – 1992) and hospitalized between 1992–1996 were retrospectively analysed.

Complicated cases were noticed: 26·2 per cent (65) – haemorrhage, 6 4 per cent (16) – perforation, 27 per cent (67) – stenosis

Correlation between primary and final diagnosis is discussed upper digestive endoscopy is mandatory (best results over CT-scan, ultrasonography and conventional X-ray)

Preferable surgical interventions were tumour resections even palliative for advanced stages of disease. Postoperative complications had a low rate only 6·4 per cent (16) anastomotic leakage, in-hospital mortality. 6·8 per cent (17)

Our data permitted us to conclude that advanced complicated gastric cancer could benefit aggressive surgery with acceptable results Rapid diagnosis in emergency conditions improved the situation.

The effect of splenectomy on morbidity and survival following gastrectomy for gastric adenocarcinoma

N.A. Kama, T. Coskun, A. Yazgan, E. Reis, M. Guler and E Kesici *Ankara Numune Hospital, 4th Department of Surgery, Ankara, Turkey*

Aim: We investigated the factors affecting the survival in the patients with gastric adenocarcinoma who underwent gastrectomy and the impact of splenectomy on survival and postoperative infectious complications.

Material and methods: One hundred and nine patients who underwent gastectomy for gastric adenocarcinoma between 1991 and 1997 have been followed up for a mean of 40 months. Twenty-nine (27 per cent) patients were female and 80 (73 per cent) patients were male, with on average age of 59·8 (range 29–87) years Seven patients were in stage I, 27 in stage II, 50 in stage III, 25 in stage IV pathologically. Twenty-nine patients (27 per cent) were node negative. Sixty-one patients (56 per cent) underwent total gastrectomy and 48 patients (44 per cent) underwent distal subtotal gastrectomy Of 109 patients, 44 (40 per cent) underwent splenectomy Chi-square test was used for statistical evaluation Survival curves were calculated using the Kaplan–Meier method

Results: There were no statistical difference between the two groups concerning age, pathologic TNM staging, curability of resection, Borrmann and Lauren classification. However, tumours were statistically larger

(<6 cm vs >6 cm, $P<0{\cdot}05$) and more invasive in the splenectomy group. Postoperative mortality was 13·6 and 7·7 per cent in the patients who underwent gastrectomy with splenectomy and without splenectomy respectively ($P>0{\cdot}05$). Eleven per cent of the patients developed infectious complications in the splenectomy group (3 wound infection, 1 pneumonia, 1 anastomotic leakage) where as infectious complications were encountered in 9 per cent of the patients without splenectomy (2 wound infection, 1 pneumonia, 2 anastomatic leakage, 1 intra-abdominal abscess) ($P>0{\cdot}05$). There was no difference between the survival times of the patients who underwent gastrectomy with curative intent with and without splenectomy respectively in the univariate analysis (mean 24 months vs 32 months, $P>0{\cdot}05$).
Conclusion: The results of this study have shown that postoperative mortality was high in the splenectomy group although this difference did not reach statistical significance. Splenectomy did not affect survival in this series. When the role of spleen on immune system is taken into consideration, it may be better to preserve the spleen unless it is directly invaded by the tumour.

Mortality and risk factors in perforated gastroduodenal ulcers

A. Kocillari, B. Elezi and E. Petrela *University Hospital Centre 'Mother Teresa' of Tirana, Dibra Str. 372, Tirana, Albania*

Recent data confirm that mortality for perforated gastroduodenal ulcers is high and decreases of it is difficult, because this is not dependent only of the methods of operations use for treatment.

There are same risk factors present at the patients at the moment of operations responsible for high mortality.

We have tried to determine this prognostic risk factors in 3605 patients who between 1 January 1965 and 31 December 1994 are treated for perforated gastroduodenal ulcers at Hospital Center of our University, Military Central Hospital and at six District Hospitals. There are 3495 patients alive (mean years 40±1·6) and 111 dead (mean years 61±2·1) (3·07 per cent). Simple suture have been used at 94·3 per cent of patients, resection 3·16 per cent, truncal vagotomy 2·35 per cent and unoperated 0·16 percent.

This study based on statistical analysis, (chi square testing) showed the following range of risk factors responsible for mortality:

– Age	$P\leq0{\cdot}001$
– Time from perforation to surgery over 24 hours	$P\leq0{\cdot}001$
– Advanced peritonitis	$P\leq0{\cdot}001$
– Shock	$P\leq0{\cdot}001$
– Concomitant diseases	$P\leq0{\cdot}001$
– Concomitant haemorrhages	$P\leq0{\cdot}001$
– Ulcer localizations	$P\leq0{\cdot}001$
– Ulcer history over 3 months	$P\leq0{\cdot}001$
– Gender	$P\leq0{\cdot}05$

Autoexpandable stent as palliation of obstructive antral carcinoma

C. López Montes, A. Ibarreta Marinelli, J.M. Martinez Romeo, J. Echarri Vázquez, E. Cebrian Tejero, J. Escudero, L. Torre Rábago, J.L. Veiga Martinez *Severo Ochoa Hospital, Leganes, Madrid, Spain*

Autoexpandable stents have previously been used in arterial, biliary, oesophageal and colonic stenosis. We introduce a new possibility of the procedure, such as palliation of a malignant, unresectable stenosis of the gastric outlet.
Case report: Seventy-three year old male with extensive adenocarcinoma of the gastric antrum. At operation (19th July 1997), the tumour was extended to transverse mesocolon, mesenteric axis and pancreas, with implants over the great omentum. Thus, it was considered unresectable and the laparotomy limited to biopsies. The patient was admitted 4 months later showing profuse vomiting and inability for oral feeding. On endoscopy the gastric antral malignant stenosis had become complete, preventing the passage of the gastroscope. Using a combined gastroscopic and radiological aid in an ambulatory setting, an autoexpandable stent was placed along the stenosis (12 December 1996), with immediate restoration of gastroduodenal transit as it was showed by the radiopaque contrast passage. The patient reassumed oral feeding 5 hours after the procedure, and was discharged in less than 24 hours. In the first month the patient returned to normal oral feeding and had 7 kg weight increase. Five months after the procedure the tumour had grown through the stent and restenosed the gastric outlet. A new autoexpandable stent was placed inside the first (12 July 1997) with resolution of the gastric obstruction. However, the patient died one week after due to massive mesenteric thrombosis.
Discussion: The placement of an autoexpandable stent to palliate the unresectable malignant gastric obstruction provided 6 months of good quality of life survival. Other alternatives would have been gastro-enterostomy or feeding jejunostomy. Both procedures require surgical intervention. In the case of gastro-enterostomy the bulky antral mass would have forced a high placement of the anastomosis in the gastric wall, thus impairing gastric emptying. Feeding jejunostomy is psychologically bad tolerated by patients, and gastro-esophageal and saliva regurgitation are not prevented.
Conclusion: The autoexpandable stent placed endoscopically is an excellent palliation for unresectable malignant stenosis of the gastric outlet. The procedure presents advantages over the surgical alternatives, as simplicity, avoidance of anaesthesia and laparotomy, ambulatory setting and excellent functional results.

The correction of endotoxicosis at stages of treatment of children with acute pathology of abdomen

V.Z. Moskalenko, S.V. Vesely, A.A. Lositsky and A.M. Moiseev
Clinic of Children's Surgery, Donetsk State Medical University, Iljicha avenue 16, Donetsk 340003, Ukraine

The purpose of the study was to optimise correction of endotoxicosis at various stages of treatment of children with acute abdominal illnesses. We investigated and compared the results of complex treatment of 40 patients with generalized appendicular peritonitis (28), adhesion obstruction (8) and intestinal intussusception (4). Twenty children received routine therapy at various stages of treatment. In a second group of 20 patients, the preoperative preparation included a session of haemofiltration of 1·5–2 times the volume. Concentration of markers of oxidative stress sharply rose in patients of the first group 3 hours after operation, corresponding to endotoxicosis IV degree. Dien conjugations reached 9·2 standard units and above, malon dialdchide (MDA) – 14·0 mgmol/g of fibre; peroxide haemolysis of erythrocytes – 25·0 per cent; middle molecules – more than 0·430 standard units of optical density. In contrast, in the second group 3 hours after operation the parameters of endotoxicosis corresponded to II degree. Peroxide haemolysis of erythrocytes fell to 15·0 per cent and below, MDA-less than 10·0 mkmol/g of fibre; dien conjuation – was less than 4·4 standard units; middle molecules – less than 0·75 standard units of optical density. Postoperative complications occurred in 12 patients of the first group (early obstruction, anastomotic leakage, progressive peritonitis and intestinal fistula). Postoperative complications were observed in 7 patients in the second group. There were no intestinal fistulas we conclude that haemosorption is a method of choice of preoperative preparation of patients with complicated severe abdominal pathology. Plasmapheresis is a method of choice in the early postoperative period. Haemosorption and xenoperfusion are helpful in some cases.

Value of panendoscopy associated with laparoscopy in the detection of stomach cancer

J. Rdes, M. Rudzki, K. Sosada, W. Żurawiński, K. Stempel and M. Martula *III Clinic of General Surgery, Silesian School of Medicine, Żeromskiego 7, 41-902 Bytom, Poland*

Lesions developing in submucous and muscular membrane of the stomach are extremely difficult to detect without the use of gastrofiberoscope with ultrasound detector.

The aim of the present study is to estimate the diagnostic value of panendoscopy associated with laparoscopy in the detection of the lesions of stomach and duodenum wall, especially those situated in submucous and muscular membrane, which are not accessible by means of conventional panendoscopy

Examination was performed after the laparoscopic cholecystectomy. Intraoperative panendoscopy was used. Stomach wall was examined first in the light of the fiberoscope and then of the laparoscope

Examination was performed in 26 randomly chosen patients The front wall, major and minor curve of the stomach, and the front wall of the duodenum was observed Seven cases of gastric or duodenal erosions and two cases of post-ulcus scars were discovered. In the places where the lesions were located, the change in the intensity of penetrating light was observed It was noted that the vascular net is more abundant in the vicinity of the lesions. The smallest lesion detected during the examination was 2 mm long. The examination together with video-recording and taking photos of the lesions lasted from 10 to 15 minutes There were no complications connected with the examination recorded

An associated panendoscopic and laparoscopic examination enables the assessment of the wall structure of the examined organ. Therefore it is possible to detect very small lesions, to estimate their range and take material for histopathological examination.

Gastric stump cancer – a review of 21 cases

M. Serralva, V Garrido, A. Ramalho, M. Oliveira, G. Santos, V. Veloso and C. Silva *Department of Surgery, Clínica Oncológica II, Instituto Português de Oncologia, Centro do Porto, 4000 Porto, Portugal*

Aim: The gastric stump cancer is a pathologically rare entity that a malignant neoplasia appears in a stomach operated on with benign pathology This study was performed to identify the anatomo-clinical characteristics of this tumour and analysed the overall 5-year survival in these patients.
Patients and methods: From January 1974 to December 1995, 1339 patients with gastric cancer were operated on in our Institution, of which 21 (1·6 per cent) had gastric stump cancer All cases were analysed retrospectively Results of the survival and latency analyses were displayed graphically using the life-table method. The mean survival was 13 months and the mean follow-up was 17 months (range 2–72 months).
Results: Nineteen patients (90·5 per cent) were men and 2 (9 5 per cent) were women, with an average age of 63 8±8·8 years (range 50–79 years). The mean time of presenting complaints was 7·9±6·7 months and the most common complaints were epigastric pain and postprandial fullness (66 per cent) followed by anorexia/loss weight (38 per cent) and by vomiting/regurgitation (28 per cent). The mean time between the first surgery and the tumour development was 27·5 years (range 10–45 years) In 20 (95·2 per cent) patients, the diagnosis was performed with endoscopic study and confirmed by biopsy. Curative resection (R0) was performed in 13 (62 per cent) patients, 2 (9·5 per cent) had palliative surgery (R1 or R2) and 6 (28·5 per cent) had exploratory laparotomy or by-pass. Nine (42 8 per cent) tumours were macroscopically vegetative, 5 (23·8 per cent) ulcerative and 3 (14·3 per cent) infiltiative On the histological study, 3 (14·3 per cent) tumours were well differentiated (G1), 8 (38 per cent) moderately (G2) and 3 (14·3 per cent) poorly differentiated (G3). In TNM classification (UICC), 5 (24 per cent) patients belonged to stage I, 2 (10 per cent) to stage II, 5 (24 per cent) to stage III and 9 (42 per cent) to stage IV Eight (38 per cent) patients were submitted to complementary treatment with chemotherapy. The curability rate was 62 per cent and the resectability tumour rate was 71 per cent Four (19 per cent) patients had postoperative complications (1 intraabdominal abscess, 1 pulmonary infection, 1 acute pancreatitis and 1 acute pancreatitis with pulmonary infection). The average length of hospital stay was 15 days. The overall 5-year survival rate was 33 per cent
Conclusions: The gastric stump cancer is a neoplasia, which showed a male preponderance In our series the mean time between the first gastric surgery and the tumour development was 27·5 years These results support the need of strict endoscopic follow-up of these patients 10–15 years after the first surgery and by this way identify the tumour in a precocious stage.

Risk factors for surgical treatment of gastric cancer with D2 dissection, Turkish experience

A.E. Unal, Ş. Atabekoğlu, M. Bozer, K. Karadayı and S. Demirci
Ankara University, Faculty of Medicine, İbn-I Sina Hospital, Department of Surgical Oncology, Sıhhıye, Ankara, Turkey

Gastric cancer is one of the most important problems in Turkey and will be the leading one in cancer deaths. The aim of this report is to discuss the results and the risk factors that effect the morbidity and mortality rates in patients having D_2 dissection in Gastric Cancer Study Group of Ankara University Faculty of Medicine, Surgical Oncology Department

The results of 300 patients were discussed who underwent surgical treatment between January 1991 and December 1996. D_2 dissection was performed routinely. Two hundred and thirty-five patients were treated with curative intent and 65 were palliative. Median age was 62 (22–75), (59 per cent) 177 of 300 patients were male.

Duration of operation, blood transfusion, age, type of gastric resection, pancreatectomy, splenectomy and other combined resections were evaluated by multivariate analysis. Hospital deaths were 7 per cent and overall complications were 28·2 per cent Age and anastomosis leakage was the most important, pancreatectomy was significant risk for hospital deaths Survival rates were tested by Kaplan–Meier test and 3-year survival rates were 65 per cent. TNM Stage, lymphatic invasion, perineural invasion, diameter of primary tumour, extension in gastric wall, number of metastatic lymph nodes and splenectomy were important risk factors for survival

Although surgical treatment of gastric cancer has shown increased rates of morbidity and mortality in patients having D_2 resection, according to our experience extended lymph node dissection is more effective modality for local control and survival.

Cancer of the stomach – does it still remain a diagnostic and surgical problem?

J. Wasiak, R. Markert, M. Gryszkiewicz and Z. Muras *Clinic of General Surgery and Transplantology, Kopcińskiego 22, 90-153 Łódź, Poland*

Gastric cancer ranks among malignant tumours that are diagnosed too late The effectiveness of its treatment is still poor. In the present study an attempt has been made to find out about the cause of this situation. The analysis was conducted of 121 patients, 74 males and 47 females aged from 32 to 83 years, operated upon for gastric cancer in the Clinic of Surgery in the years 1988–97 (1·1 per cent of all persons operated during this period of time). Under 50 years of age were 10 per cent of them, and over 70 yr – 38 per cent. Their history length and preoperative symptoms were assessed The discussed 10-year space of time was divided into two 5-year periods, and in each comparison was made between the diagnostic findings obtained and the kinds of surgery performed. Age proportions of the operated persons were almost unchanged. In the years 1988–92 inoperable gastric cancer occurred in 44 per cent of cases, and in the years 1993–97 in 28 per cent of cases. An almost twofold increase in the number of resection procedures (27 per cent to 48 per cent) was noted.

Conclusions:

1 The diagnostic investigations in gastric cancer are performed too late despite the early appearance of the first symptoms.

2 In a considerable number of patients the disease runs an asymptomatic course.

3. During the last 5 years a rise in the percentage of resection procedures among the patients studied was observed.

Results of surgical treatment in proximal and distal gastric cancer

M. Wyleżoł and M. Pardela *2nd Department of General and Vascular Surgery, Silesian University School of Medicine, ul. M. Curie-Skłodowskiej 10, 41-800 Zabrze, Poland*

A retrospective study was performed on 468 consecutive patients operated between 1985 and 1997 in our department with gastric cancer Comparison of material and results was done due to localization in prox-

imal (PPS) and distal (DPS) part of the stomach. There were 210 (44·9 per cent) patients in PPS and 258 (55·1 per cent) in DPS group. In women localization was more often in distal part with significant difference $P<0·001$ [PPS: nM=161 (76·7 per cent), nF=49 (23·3 per cent); DPS: nM=159 (61·6 per cent), nF=99 (38·4 per cent)]. Patients in PPS were significantly younger than in DPS group – $P<0·005$ (PPS-56(13); DPS-60(11)).
Resections: PPS n=157 (74·8 per cent), DPS n=214 (82·9 per cent) $P<0·05$; between them curative: PPS n=52 (33·1 per cent), DPS n=96 (44·8 per cent) $P<0·01$. This difference was significantly accompanied with appearance of stage IIIb and IV (WHO classification) in both groups: PPS n=161 (76·7 per cent) and DPS n=162 (62·8 per cent) ($P<0·005$).
Early results: 37 (17·6 per cent) patients died in PPS and 28 (10·9 per cent) in DPS group ($P<0·05$). 5-year survival rate – among curative restrictions – in PPS group was 36·5 per cent and in DPS 53·1 per cent ($P<0·05$).
Conclusions: Epidemiological differences and bad prognosis in PPS group suggest that new treatment protocols should be designed to include the location of the neoplasm.

Palliative resection of cardia cancer with mechanical and manual reconstruction of digestive tract in our department

M. Wyleżol, M. Pardela and W.K. Karcz *2nd Department of General and Vascular Surgery, Silesian University School of Medicine, ul. M. Curie-Skłodowskiej 10, 41-800 Zabrze, Poland*

We performed retrospective analysis of 105 consecutive patients with cardia cancer underwent palliative resection in our department between 1985 and 1997. Two groups of patients with different type of anastomosis sutures were compared: mechanical 78 (74·3 per cent) and manual 27 (25·7 per cent). There were no significant differences in sex, age, duration of symptoms, weight loss, size of the tumour, neoplastic infiltration, metastases and in the histopathological examination. In the mechanical group all patients were operated by opening abdomen cavity. Mean duration of operating procedure in this group was 230±58 min ($P<0·005$). The most dangerous postoperative complication – anastomotic leakage was noted in 2 (2·56 per cent) patients. Mortality reach 11·5 per cent (n=9) in early postoperative period, death caused by pulmonary insufficiency was noted in 3 (3·84 per cent; $P<0·05$) cases. In the second group during the operation procedure have had to perform also thoracotomy in 15 (55·5 per cent) cases ($P<0·001$). The procedure was longer 290±93 min ($P<0·005$). The main postoperative complication – anastomotic leakage was observed in 2 (7·4 per cent) cases. Mortality rate was on the level of 33·3 per cent (n=9) in early postoperative period and the pulmonary insufficiency deaths were more frequent 6 (22·2 per cent; $P<0·05$) patients. Mechanical staples should be used because of the shorter operation time and advantage of abdominal cardiectomy. We did not observe significant difference in anastomotic leakage between both groups of patients.

Reliability of preoperative staging of gastric adenocarcinoma by imaging techniques

A. Yazgan, N.A. Kama, T. Coskun, M. Doganay, E. Kesici and A.Z. Akat *Ankara Numune Hospital, 4th Department of Surgery, Ankara, Turkey*

Aim: Ultrasonography (US) and computerized tomography (CT) are the most and frequently used imaging methods to determine the extent of gastric adenocarcinoma preoperatively. In this study the reliability of preoperative staging with US and CT was assessed in the patients with gastric adenocarcinoma.
Material and method: The difference between the preoperative and pathological staging were studied in 132 patients who underwent laparotomy for gastric adenocarcinoma between 1991–1997. Thirty-five patients (27 per cent) were female and 97 (73 per cent) were male. Seven patients were in stage I, 27 in stage II, 50 in stage III, 48 in stage IV pathologically. Twenty-eight patients had peritoneal metastasis and 29 patients had liver metastasis. Statistical analysis was done by using chi-square test.
Results: In preoperative evaluation, there were 32 patients in stage I, 59 patients in stage II, 17 patients in stage III and 24 patients in stage IV. However, in pathological evaluation there were 7 patients in stage I, 27 patients in stage II, 50 patients in stage III and 48 patients in stage IV. The patients were found to be understaged by clinical evaluation when compared with pathological assessment ($P<0·0001$). The sensitivity, specificity and accuracy of US and CT were shown in Table 1.

	Peritoneal metastasis		Liver metastasis	
	US	CT	US	CT
Sensitivity	8	15	77	76
Specificity	100	100	95	100
Accuracy	80	77	95	93

Conclusion: These findings showed that patients were falsely understaged with preoperative staging probably because of the inaccuracy of US and CT in demonstrating peritoneal metastasis.

The effect of resection type on mortality and morbidity in gastric adenocarcinoma

A. Yazgan, N.A. Kama, E. Reis, U. Gozalan, M. Guler and A.Z. Akat *Ankara Numune Hospital, 4th Department of Surgery, Ankara, Turkey*

Aim: In this study, we compared total gastrectomy (TG) with distal subtotal gastrectomy (DSG) concerning postoperative morbidity and mortality.
Material and methods: Between 1991–1997, 61 patients underwent TG and 48 patients DSG because of gastric carcinoma. Mean follow-up time 40 months. Twenty-nine (27 per cent) patients were female and 80 (73 per cent) were male, with an average age of 59·8 years (range 29–87). In TG group, 2 patients were in stage I, 15 in stage II, 29 in stage III, 15 in stage IV, in DSG group, 5 patients were in stage I, 12 in stage II, 23 in stage III and 10 in stage IV pathologically. Four patients in TG group and 3 patients in DSG group underwent emergency laparotomy because of tumour perforation in three patients and tumour bleeding in four patients. In TG group Roux-en-Y oesophagojejunostomy, in DSG group Billroth II gastrojejunostomy reconstruction types were preferred. All anastomoses in both groups were performed manually. The tumour was in middle third in 8 and lower third in 40 patients in DSG group and 19 in upper third, 28 in middle third, 4 in lower third of the stomach in TG group. Splenectomy was performed in 40 patients in TG and in 4 patients in DSG group. Chi-square test was used for statistical evaluation.
Results: There were no statistical difference between the groups concerning age, curability of operation, tumour differentiation, tumour size, pathologic TNM staging. The 4-year cumulative survival rates were 4 per cent and 5 per cent in TG and DSG groups respectively. The mean number of removed lymph nodes was 12 in DSG group and 20 in TG groups ($P<0·05$). The mean number of metastatic lymph nodes was 5·2 in DSG group and 9 in TG group ($P=0·09$). No statistical difference was found between DSG and TG groups concerning perioperative blood transfusion (46 per cent vs 58 per cent), anastomotic leakage (0 per cent vs 5 per cent) and postoperative mortality (6 per cent vs 13 per cent).
Conclusions: Although postoperative complication and mortality rates were slightly higher in total gastrectomy group than in distal subtotal gastrectomy group this difference did not reach statistical significance. The results of this study have revealed that TG can be performed with an acceptable mortality and morbidity rates when compared with DSG in the treatment of gastric adenocarcinoma.

Useful and useless diagnostic procedures in oesophageal cancer

M. Aleksic, N. Hennes and B. Ulrich *Dept. of Surgery, Gerresheim Hospital, Gräulinger Str. 120, 40625 Düsseldorf, Germany*

Aim: After confirming the diagnosis of oesophageal cancer by endoscopy and biopsy all further diagnostic measures are initiated to clarify general operability and surgical resectability in particular.

The decision whether to introduce any neoadjuvant treatment and its follow-up examinations are based on preoperative staging procedures, too.

Finally the surgical approach is chosen according to the localization and extension of the tumour established by those imaging techniques.

Materials and methods: Analysing data of 150 patients with cancer of the esophagus who were treated in our department from January 1987 until April 1997 the validity of the various examinations are interpreted.

Results: In 35 patients the tumour was not resected (resection rate: 77 per cent). This could be referred to additional informations obtained by thoracic and abdominal CT-scan in only four cases. In total the results of CT-scans lead to consequences for the further treatment in 15 per cent (22/150).

Endoluminal ultrasound was performed in 60 patients since 1993. Compared to the postoperative histopathological classification the T-stage was correctly assessed in 50 per cent (23/46: in 14 patients there was no histopathological matching available) whereas metastatic lymph node enlargement was detected in 65 per cent (27/46).

In tumours of the proximal and middle third bronchoscopy was employed to rule out any infiltration of the tracheobrochial system which then was found in 8 patients out of 30 (24 per cent) who did not undergo resection.

If it was possible to pass the tumour stenosis by endoscope, in 86 per cent (83/96) any additional diagnostic procedure did not interfere with the treatment.

Conclusion: Due to limited logistic and financial sources the routinous use of especially technical techniques for preoperative staging in oesophageal cancer should be reevaluated.

Transhiatal oesophagectomy: management of intraoperative complications

D. Chosidow, J.P. Marmuse, D. Amsellem, J.H. Maillochaud, H. Johanet and G. Benhamou *Hôpital Bichat-Claude Bernard, 46 rue Henri Huchard, 75018 Paris, France*

Transhiatal Oesophagectomy (THO) intraoperative complications are rare but serious. The aim of this retrospective study is to assess the rate and the type of THE intraoperative complications without thoracotomy.

Material and methods: From 1986 until 19976, 270 THO were consecutively performed either for carcinoma of the oesophagus (200), benign disease of the oesophagus (n=30), or for other disease (n=40). The technique includes constant opening of the pleura, therefore pneumothorax is not a complication.

Results: Complications occurred in 5 cases (1·8 per cent) and were of two types: vascular (2) and tracheal (3). All of these complications were diagnosed peroperatively.

Vascular wounds were diagnosed in view of massive bleeding. In the first case it was venous bleeding, a right anterolateral thoracotomy was immediately performed allowing suture and hemostasis of an azygos vein wound. In the second case bleeding was uncontrolled, haemodynamic failure occurred. An immediate left anterior thoracotomy was performed. Bleeding came from an aortic branch wound which was immediately sutured allowing good hemostasis.

Three tracheal lacerations occurred during blunt dissection. One, involving the high membranous trachea was sutured through a partial upper sternal split. The second involved the membranous carina: THO was completed with retro sternal by-pass. Then, changing the selective ventilation to the left main bronchus, a right postero lateral thoracotomy was performed and tracheal suture done. The third involved cervical trachea and was sutured through the cervical incision. Concerning tracheal complications, two of them resulted from overinflated tracheal cuff and the third occurred after difficult intubation. In these three cases, postoperative artificial ventilation was shorter (less than 48 hours) to avoid high pressure on the tracheal sutures.

Among these 5 patients, one had postoperative pneumonia. No other complications occurred. None of these 5 patients died.

Conclusion: Intraoperative complications occurring during THO are rare (1·8 per cent) but serious. They require urgent management by thoracic approach.

Therefore, solid experience in thoracic surgery is needed to perform THO safely.

Oesophageal motility after modified Sugiura procedure

T. Drączkowski, D. Zadrożny and M. Olędzki *I Department of Surgery, Medical University of Gdańsk, Dębinki 7, 80-211 Gdańsk, Poland*

Aim: Evaluation of oesophageal motility in cirrhotic patients with esophageal varices subjected to modified Sugiura procedure.

Material: Extensive gastro-esophageal devascularization and oesophageal transection is the method of choice in treatment of bleeding oesophageal varices after failure of sclerotherapy. It ensures control of variceal bleeding without loss of hepatic portal perfusion. Nevertheless such an extensive operation raises the question of its influence on oesophageal motility. It is also controversial how does acid reflux affect the varices and what role does it play in initializing variceal haemorrhage. Thirty-seven patients with hepatic cirrhosis and oesophageal varices were evaluated for gastro-oesophageal reflux and oesophageal motility disorders. Standard 24-hour pH-metry, and combined 24-hour pH and manometry were used. Preoperative pH values confirmed reflux in 58 per cent of patients. They did not differ significantly after the operation. Twenty-four-hour manometry showed significant degree of peristaltic dysfunction, in the form of insufficient and 'dropped' peristaltic sequences. On the other hand, contractile action in the distal oesophagus showed proper manometric values. All analysed parameters also did not differ significantly before and after the operation.

Conclusions: In our material gastro-oesophageal reflux occurred in 58 per cent of cirrhotic patients. Manometric measurements confirmed impaired motoric function in cirrhotic patients with varices. The results did not differ significantly after oesophageal transection. Data obtained from 24-hour pH-metry suggest, that the operation did not cause significant increase of G-E reflux.

Palliation of inoperable oesophageal carcinoma treated by self-expanding stents

A. Güemes, M.A. De Gregorio, J.C. Salinas, J. Torcal, R. Sousa, F. Burdío, J. Fernández and R. Lozano *Departments of Surgery and Interventional Radiology, University Hospital Zaragoza, Avda. San Juán Bosco 15, 50010 Zaragoza, Spain*

Introduction: Less than 40 per cent of oesophageal carcinoma can be treated with conventional curative surgical procedures. Dysphagia is the main complaint of these patients, even in 20 per cent of curative surgically resected patients. Endoscopic laser therapy (ELT) and self-expanding stents (SES) are used for palliation. ELT has the lowest rate of complications but the dysphagia-free interval does not last longer than for 4–6 weeks. SES have been shown to be superior to conventional rigid plastic endoprostheses allowing a large self-expanding diameter and a rapid palliation of symptoms.

Aim: To evaluate our experience in the treatment of inoperable oesophageal carcinoma using metallic self-expanding stents.

Patients and methods: This is a retrospective study of the SES placed for palliation of malignant oesophageal strictures. Since January '93 until March '97, 80 SES were placed in 78 patients (mean age: 60·6 years, range: 34–85; 70 males and 8 females). Inclusion criteria were: 1) Locally advanced disease; 2) Systemic disseminated disease (M1); 3) Poor general conditions, and 4) Patients who rejected surgery. Covered stents (Wallstent, Gianturco-Rosch, Strecker) and non-covered stents (Strecker, Wallstent) were used. Twenty-two per cent of patients received neoadjuvant radiotherapy and 35 per cent chemotherapy plus radiotherapy. Dysphagia score was used for palliation criteria. patients were evaluated every month until death.

Results:

Dysphagia score	0	1	2	3	4
Pretreatment dysphagia (%)			8·7	31·3	60
Posttreatment dysphagia (%)	64·6	30·4	5		

Data presented as percentage of patients.

Fifty patients had oesophageal adenocarcinoma and 28 sqamous cell carcinoma. There were no differences in the palliation according to pathological findings or location of the stricture. 76·7 per cent had a stricture at the upper or medium oesophagus and 23·3 per cent at the lower oesophagus. 97·9 of the SES were successfully inserted but 6 per cent of them needed to be replaced. Six per cent had to be dilated with balloon catheter. Placement complications were bleeding (9·09 per cent), chest pain (29·2 per cent). Long term complications were recurrent dysphagia (35·4 per cent), migration (5·3 per cent), tumour ingrowth (46·4 per cent), tumour overgrowth (4 per cent), food-bolus impaction (7·7 per cent). Mean duration of hospitalizatrion were 4·9±1·2 days. Mean survival time were 125·5 days.

Conclusions: SES can be used safely for dysphagia palliation in cases of unresectable esophageal carcinoma.

Coated vs uncoated self expanding stents in the treatment of malignant oesophageal strictures

A. Güemes, M.A. De Gregorio, R. Sousa, J.C. Salinas, F. Burdío, J. Torcal, J. Fernández and R. Lozano *Departments of Surgery and Interventional Radiology, University Hospital Zaragoza, Avda. San Juán Bosco 15, 50010 Zaragoza, Spain*

Background: Esophageal obstruction due to cancer can produce debilitating symptoms such as dysphagia and aspiration pneumonia. Obstruction could be caused by esophageal and bronchial tumours infiltrating mediastinum. Laser therapy is not always indicated in cases of extrinsic compression, requires repeated sessions and is not free of complications. Oesophageal prosthesis (SES) can easily relieve the symptoms allowing oral feeding for a long time. Uncoated self-expanding stents (USES) have been used for dysphagia palliation for a long time, but tumour ingrowth can prevent for a complete dysphagia relieve. Coated self expanding stents (CSES) were developed to avoid tumour growth inside the lumen allowing a longer symptom free interval.

Aim: This is a comparative study between the USES and CSES in the palliative treatment of malignant oesophageal strictures. Retrospective study.

Material and methods: Since January '93 until March '97, 101 SES were placed in 99 patients (mean age: 60·6 years, ranged: 34–85; 70 males and 8 females). Inclusion criteria were: 1) Locally advanced disease; 2) Systemic disseminated disease (M1); 3) Poor general conditions, and 4) Patients who rejectes surgery. Covered stents (Wallstent, Gianturco-Rosch, Strecker) were used in 27 patients (27·2 per cent) and non-covered stents (Strecker, Wallstent) were used in 72 patients (72·7 per cent). All endoprostheses were deployed successfully in the desired location but two needed balloon dilation. Visick Dysphagia score was used for palliation criteria. Patients were evaluated every month until death.

Results:

	Histological type				Location			
Stent type	Squamous	Adeno-carcinoma	Bronchial carcinoma	Others	Upper	Middle	Lower	Associated fistula
CSES	14	6	6	1	12	10	5	16
USES	42	16	13	1	37	17	18	1

Data presented as percentage of patients.

Eight patients in the USES groups had a complication (migration $n=3$, toracic pain $n=1$, bleeding $n=2$, obstruction $n=2$) and only one patient in the CSES group (bleeding). Dysphagia improved in all but one patient in the CSES group and in all but 5 patients in the USES group, moderate dysphagia appeared in 2 patients in the CSES group and in 38 patients in the USES group. One patient died at the 14th postoperative day because of aorta-oesophagus fistula due to migration of the prostheses.

Conclusion: Both CSES and USES are useful in the treatment of inoperable malignant stenosis of the oesophagus. Both prostheses can be safely placed with a low rate of complications. CSES seem to be superior to USES in the long-term relief of dysphagia.

The value of surgery in oesophageal perforations

Gy. Lázár, T. Oláh*, V. Szendrényi**, K. Szentpáli and A. Balogh *Department of Surgery, Albert Szent-Györgyi Medical University, 6701, PO Box 464, Szeged, *City Hospital of Szeged and **Dunaújváros, Hungary*

Introduction: The aim of our study was to evaluate effectivity of the surgical treatment for oesophageal perforation caused by various incidents.

Patients: Between 1991 and 1996, 11 patients with perforation of the oesophagus were treated in the department. The mean age was 54 years (range 24–68); 4 patients were female. The perforation was located in the cervical part of the oesophagus in 5 cases, and in the thoracic part in 6 cases. Blunt neck trauma in 1 case, foreign body and accidental intubation in 2 cases each had led to perforation of the cervical oesophagus. The aetiology of the intrathoracal oesophageal perforation was Boerhaave's syndrome in 3 cases, iatrogenic in 2 cases, and Barret ulcer perforation in 1 case.

Results: The treatment for cervical oesophageal perforation consisted of antibiotics, nasogastric tube or gastrostomy, total parenteal nutrition, and surgical suction drainage. All 5 cases recovered completely. In the cases of intrathoracal oesophageal perforation, within 24 h of the onset, the surgical treatment was suction drainage and primary closure of the leakage with gastrostomy (3 patients). Three patients presented late (>24 h after the incident). In these cases, the surgical treatment consisted of oesophagectomy, cervical oesophagostomy, mediastinal drainage and feeding gastrostomy. In spite of aggressive surgical treatment, one patient died due to mediastinitis and severe sepsis. In the remaining 2 cases, the alimentary tract was reconstructed with ileocolon.

Conclusions: The prognosis of oesophageal perforation depends essentially on the perforation site and the time of diagnosis. Cervical oesophageal perforation responds well to surgical treatment. In intrathoracal oesophageal perforations primary reconstruction is suggested only after an early diagnosis. After 24 hours of the onset resectional surgery has given good results for intrathoracic oesophageal perforation.

Thorascopic assisted transhiatal oesophagectomy – new lamps for old?

M.K. Lingam and G. Bell *Department of Surgery, Inverclyde Royal Inffirmary, Greenock, Scotland*

Surgical excision remains the best chance of long-term survival for patients with oesophageal carcinoma. The advent of minimal access surgery allows accurate dissection and thorascopic mobilization of the oesophagus without the need for thoracotomy and its associated complications. We report our experience of thorascopic-assisted transhiatal oesophagectomy (TATH) between December 1993 and June 1996. Forty-two consecutive patients underwent TATH. Twelve patients required conversion to thoracotomy because of pulmonary adhesions, size of tumour, tracheal injuries or ventilation difficulties. The mean age of the patients was 65·7 (45–80) years. The stricture length was between 3–11 cm in the TATH and 5–12 cm in the conversion group. Average total operation time was 308 minutes (235–400) in the TATH, thoracoscopic dissection taking 83 minutes (50–120). One death occurred in each group. The mean postoperative hospital stay was 14 days in both groups. The 1 and 2 year survival rates were 71 per cent (30 of 42) and 60 per cent (25 of 42) respectively. The results of TATH are very similar to those of conventional surgery. We propose that TATH may offer an advantage in terms of visualization of mediastinal structures during dissection, thus minimizing operative complications.

Pulmonary complications following transhiatal oesophagectomy in patients with severe chronic obstructive pulmonary disease

J.H. Maillochaud, J.P. Marmuse, D. Chosidow and G. Benhamou
Hôpital Bichat-Claude Bernard, 46 rue Henri Huchard, 75018 Paris, France

Transhiatal esophagectomy (THE) was proposed in order to reduce the incidence and the severity of postoperative pulmonary complications (PC). Certain surgical teams reserved THE for patients who are unsuitable for a transthoracic oesophagectomy, notably when there coexists a severe chronic obstructive pulmonary disease. The aim of this study is to assess this approach by evaluating the influence of preoperative pulmonary function on the pulmonary morbidity and mortality following THE.

Material and methods: From 1986 to 1994, 136 THE were consecutively performed for carcinoma of oesophagus. There was 111 men and 25 women with a mean age of 60 years (range 36 to 91). The patients were divided into two groups: those with a forced expiratory volume in one second (FEV) lower than 60 per cent of the theoretical value (*n*=19), indicating severe chronic obstructive pulmonary disease and those with a FEV higher than 60 per cent of the theoretical value (*n*=117). A major PC was defined as requiring initial assisted ventilation higher of more than 48 hours or requiring endotracheal reintubation for a respiratory failure. The other PCs were considered minor.

Results: PC occurred in 36 patients (26 per cent). The respiratory mortality rate was 3 per cent (*n*=4). Comparison of the two groups showed:

	IC stay	Total PC	Minor PC	Major PC	Respiratory mortality
FEV >60%	8·0±4·2	25% (*n*=29)	18% (*n*=20)	8% (*n*=9)	1·6% (*n*=2)
FEV <60%	9·3±11·6	36% (*n*=7)	14% (*n*=3)	21% (*n*=4)	10% (*n*=2)
P value	0·067 (n.s.)	0·31 (n.s.)	0·78 (n.s.)	0·05 (s)	0·094 (n.s.)

Conclusions: Severe chronic obstructive pulmonary disease did not significantly increase pulmonary morbidity rate following THE.

However, PC occurring in this group of patients appeared more severe with a significant increase in major PC and respiratory mortality rates.

CYFRA 21-1 – its implication as a prognostic factor for the squamous carcinoma of the esophagus

H. Bottberg, J. Brockmann, J. Kocik and N. Senninger *Dept. of Surgery, University of Münster/Germany, Waldeyerstraße 1, 48149 Münster, Germany*

Introduction: Up to now there is no reliable tumour marker for malignant diseases of the oesophagus. Some studies from the last three years indicate the role of the marker CYFRA 21-1 as a prognostic factor in squamous lung cancer.

Aim: Evaluation of the role of CYFRA 21-1 as a prognostic marker for the squamous cell carcinoma of the esophagus.

Patients and methods: Sera of 35 patients suffering from squamous cell carcinoma of the esophagus were examined in a prospective trial. Blood examinations were made before surgery and during the follow-up one year after the operation. Statistcal analysis was done using the one sample t-test.

Results: The concentration of CYFRA 21-1 showed significant correlation to the local tumour growth. The mean concentration was 1·29 ng/ml in case of early cancer of the oesophagus (*n*=6), 1·50 ng/ml [T2, *n*=9], 2·07 ng/ml [T3, *n*=16] and 2·43 ng/ml [T4, *n*=3]. There was no statistical significance in substance concentration with regard to the nodal status or in case of distant metastases.

Conclusion: CYFRA 21-1 is a useful marker indicating the extent of local tumour growth but fails to indicate lymph node metastases and distant metastases in squamous oesophageal cancer.

Transoral application of EEA stapler after subtotal oesophagectomy

J. Škultéty, M. Žiak, P. Labaš, Š. Durdík and J. Sekáč
Department of Surgery, Faculty Hospital, Mickiewiczová 13, 821 01 Bratislava, Slovakia

The authors describe successful usage of EEA Stapler for reconstruction after subtotal oesophagectomy for spinocellular carcinoma in middle third and in distal third of oesophagus in two patients. In both cases EEA stapler was applicated *transoral and made oesophagogastric anastomosis.* We had no complications pre- or postoperatively. Patients left clinic on 14th or 21st day after operations. Authors consider transoral application of EEA stapler to be good alternative for cervical oesophagogastric anastomosis after subtotal oesophagectomy.

Mortality of patients after resection for oesophagus carcinoma is frequently caused by dehiscent of oesophagogastric anastomosis. Change in principle was to initiate subtotal oesophagectomy as treatment of oesophageal carcinoma or other benign diseases, which require to removal of the oesophagus. 'Blunt dissection' is the main contribution. Reconstruction after this oesophagectomy requires the creation of a cervical anastomosis, which eventual dehiscence is not as fatal a complication as dehiscent of oesophagogastric or oesophagocolonic anastomosis situated in thoracic cavity. *Cervical anastomosis is possible manually or mechanically.* Advantages of instrumental anastmosis are generally known. *Problems are practical* application of available staplers in cervical area. The orifice of tunnel, which is formed *orthotopic or retrosternal, is relative narrow what limits manipulation with implantate,* tubulized stomach or thick intestine. Resection of sternoclavicular joint after successful oesophagectomy, which gives us better anatomical conditions for manipulation in the upper thoracal apertura, seems to traumatize excessively.

Effectivity of endoscopic oesophageal intubation in the palliation for advanced, oesophagus cancers

K. Szentpáli, V. Szendrényi*, T. Oláh**, T. Lázár and A. Balogh
*A. Szent-Györgyi Medical University, Department of Surgery Szeged, *City Hospital Dunaújváros, **City Hospital of Szeged, PO Box 464, H-6701 Hungary*

Introduction: We evaluate the results of a series of 86 patients undergoing insertion of endoprosthesis (Rüsch) for palliation of inoperable oesophageal cancer.

Patient and methods: Between 1990 and 1997 we performed endoscopic intubation of the oesophagus in 86 cases because of inoperable oesophagus cancer. The patients had a mean age of 59·62 years, and the male to female ratio was 5:1. The tube insertion was managed under intravenous sedation. We used pulsion technique for the endoscopic intubation. The tumorous stenosis was dilated by Savary–Gilliard dilators. Most of the cases were not necessary X-ray control under the procedure. Thirty-six of 86 cases (41·8 per cent) we managed the intubation ambulatory. There was no mortality during hospitalization. After the intubation generally we precipitate minimal bleeding in 48 cases (55·8 per cent) but blood transfusion was not needed in any of the cases. In most cases retrosternal chest pain and 20 per cent of the cases subfebrility or fever appeared. In one case collar subcutaneous emphysema, pain, fever appeared, but contrast fluid 'outcome' was not identified by X-ray examination, surgical intervention was not necessary. Ten patients (11·6 per cent) have been admitted again with the occlusion of the tube, but endoscopic cleaning was succesful in all of them. We recognized tube migration in 9 cases (10·4 per cent). Most of the patients were able to have normal or semisolid food. The median survival was 18 weeks.

Conclusion: The endoscopic intubation of the esophagus is a safe, effective palliation for inoperable esophagus cancers. The method has numerous advantages as: might be ambulatory procedure, general anaesthesia not necessary, low morbidity, gives good quality of life.

Squamous cell carcinoma of the thoracic oesophagus following radiation therapy for breast cancer

P. Ténière, M. Scotté, G. Perrier, Y. Graïc, I. Leblanc and F. Michot *Service de Chirurgie Générale et Digestive, CHU Rouen, France*

Radio-induced cancer is a rare pathology since only 30 cases of squamous cell carcinoma of the thoracic oesophagus following irradiation therapy for breast cancer have been reported to date. To be considered as a radio-induced cancer, these tumours must fulfil such criteria as a previous irradiation, the occurrence of cancer in the irradiated area, a sufficiently long period between irradiation therapy and the emergence of the tumour, the absence of other risk factors and a sex ratio different from usual ratio.

Between 1981 and 1995, among 3622 patients treated by mediastinal irradiation for breast cancer, we observed five cases of radiation-induced squamous cell carcinoma of the thoracic oesophagus. They were four women and one man (age 48–80) with no previous history of either smoking or alcohol abuse. The mean interval between irradiation and presentation with oesophageal cancer was 12·8 years (7–21). The tumour always appear in the irradiated area and was in all cases a squamous cell carcinoma. Treatment consisted of radiotherapy only, oesophagectomy, laser photocoagulation for a superficial tumour, and palliative treatment for two patients suffering from an advanced stage cancer with tracheal invasion, respectively.

These observations and the analysis of the literature indicate that: 1) radiotherapy treatment of the oesophageal cancer (exclusive or adjuvant) should take into account previous oesophageal radiation treatment; 2) the indications of curative excision surgery are the same as for other types of oesophageal cancers, but the anastomoses should be performed in a non-irradiated area; 3) excision by oesophageal stripping without thoracotomy is contraindicated because of the presence of peri-oesophageal sclerosis; 4) preventive measures in irradiation therapy for breast cancer are suggested.

Complications of endoscopic palliation of oesophagus cancer

P. Tóth, I. Kovács, S. Sz. Kiss and P. Sápy *2nd Department of Surgery, University Medical Schoolof Debrecen, Móricz Zs. str. 22, 4004 Debrecen, Hungary*

Aim: There is a great importance of the palliative treatment of oesophageal cancer because without different types of palliation the patients with inoperable oesophageal cancer have a poor quality of life. The predominant symptom is the various severity of swallowing inability that eventually progresses to complete dysphagia with hypersalivation, aspiration, rapid weight loss which eventually lead to death. The results of the surgical procedures of gastrostomy and jejunostomy are uncertain beause they are unable to prevent the complications caused by obstruction and aspiration. The aim of this study is to investigate the aspects of the procedure of palliative endoscopic oesophageal intubation that make possible to avoid gastrostomy and jejunostomy and to investigate the complications related this method.

Materials and methods: The palliative endoscopic intubation was entered in 1992 in our surgical department. Our procedure of endoscopical intubation is a simplified way of the method described by Tytgat in 1986. During the last five years 73 consecutive patients were treated with palliative fiberoscopic intubation with Tygon prothesis. Forty-six patients had esophageal carcinoma, 19 had tumours of the oesophago-gastric junction, 8 had pulmonary carcinoma obstructing the gullet. Among them 11 patients had broncho-oesophageal fistula. After the palliation the patients received High Dose Rate (HDR) after loading radiotherapy and telecobalt external treatment.

Resuls: After the endoscopical intubation the ability of swallowing improved in all of the cases and the bronchooesophageal fistulas were occluded. The complications were divided into three groups: early, late complications and other problems not related to the surgery. The early complications were perforations (7 patients), bleeding (1 patient). Two patients (2 per cent) died because of sepsis. The late complications were: food impaction (5 patients) tumour overgrowth (5 patients), tube migration in two cases when the tube moved proximally and was replaced by reintubation. We found the complaints of the reflux in all of the cardial tumorous cases. We found increase of body weight in 14 cases. Nineteen patients received intraluminal after loading radiotherapy.

Conclusions: The risk of perforation during endoscopical intubation is high, especially in the patients with tumours of distal oesophagus and the oesophago-gatric junction. On the base of previous data the rate of perforation after operative intubation is low, that is why the operative intubation is advised. The operative exploration is also a useful procedure because of the uncertainty of the CT and other examinations, and gives the possibility for the intraoperative staging and the checking of the position of the tube, as well. The improvement of quality of life is such an important result of the treatment as the improvement of the survival time due to better nutrition.

Long term results with pre-, postoperative and palliative LDR after-loading irradiation of oesophageal tumours

Z. Vígváry, E. Makó, Z. Tarján, P. Kupcsulik*, J. Faller** and Á. Balázs* *Dept. of Radiology and *1st Dept. of Surgery, **Dept. of Surgery, Semmelweis Medical University, Ulloi ut 78/a, 1082 Budapest, Hungary*

Aim: Five years survival of oesophageal tumours is 7–10 per cent. To improve survival and quality of life, lumen restricting tumours were palliatively and preoperatively treated with LDR after-loading irradiation, 5FU chemotherapy, metallic stenting and enteric food preparations.

Materials and methods: Two hundred and nineteen patients, plus 72 patients preoperatively and 29 patients with recidive tumours were treated between 1982 and 1992. The dose delivered in 3 or 4 fractions was 50 Gy, protracted by 24 h, from a 5 mm distance to the mucosal layer. For setting up correct diagnosis and staging esophagoscopy, radiography, US and CT and iosotope examinations were carried out. Survival times and quality of life were assessed. The results were compared with the control group of 46 patients, who were refusing any treatment.

Results:

Survival	– preoperative	24 patients	39·6 months
	– recidive	15 patients	25·1 months
	– inoperable	219 patients	11·6 months
	– control	46 patients	8·2 months
Quality of life	– decreasing of dysphagia		69%
	– increasing of body weight		54%
	– diminishing of pain		74%

Conclusions: LDR Cs-137 after-loading method combined with chemotherapy and enteric food preparations proved to be efficient and significantly increases survival in preoperative and recidive cases of oesophageal tumours.

VIDEO PRESENTATIONS

Hernia and Abdominal Wall

The plug technique in umbilical hernia

P. Costa, C. Martinez and C. Oliveira *Serviço de Cirurgia 3, Hospital de S. João 4200, Porto, Portugal*

Aim of this study: The aim of this video is to demonstrate the surgical correction of an umbilical hernia with a prosthetic plug of mersilene mesh.

Materials and methods: We operated a female patient, 64 years old with umbilical hernia.

Steps of the procedure: 1) periumbilical incision and dissection of the hernia sac; 2) opening the sac and resection of incarcerated omentum; 3) excision of excessive sac tissue and closure of the opened sac; 4) set the plug in the umbilical orifice, to fill all the defect; 5) fixation of the plug, with the multiple stitches, to the umbilical borders; 6) closure of the wound.

Summary of results: The patient did well, was discharged of hospital in the next day to the operation and did not require analgesics at home. After a six month follow-up there was not recurrence of the hernia.

Conclusion: Plug technique, in umbilical hernia, is easy, safe and with no recurrence in our experience.

Infection

Protection by double gloving and reinforced gown: randomized evaluation using an electronic alarm contact detector

J.L. Caillot, C. Cote, C. Lemaire, H. Abidi and J. Fabry *Centre Hospitalier Lyon-Sud, 69495 Pierre-Benite, France*

Assessing the efficacy of the surgeon–patient barrier, a randomized controlled trial was designed with four crossed-over groups: simple or double gloves, and simple or reinforced gowns.

The Elper® device (Igea, Carpi, Italy) – a contact detector triggering an audible alarm – was used, controlled by a water leak test (American Standard for Testing Material). Glove perforations and glove or gown porosity were studied. 79 surgical procedures were monitored from January to April 1996 (238 surgeon-hours), by the same surgical team (151 person-procedures).

The highest alarms' rate were observed with wet gowns (32 alarms per 100 surgeon-hours), glove perforations (13 alarms per 100 surgeon-hours) and glove porosity (11 alarms per 100 surgeon-hours). The risk of glove perforation was higher in deep surgery (with visceral contact) than in superficial surgery (RR = 2·5; CI95 per cent: 1·2–5·3). The surgeons were unaware of 81 per cent of glove perforations. The rate of procedures with alarm(s) was lower with double compared to simple gloving (RR=0·6; CI95 per cent: 0·4–0·8), as for the rate of alarms per 100 surgeon-hours (RR=0·3, CI95 per cent: 0·2–0·4). Use of reinforced gowns showed no apparent benefit compared to simple gowns, whether for the rate of procedures with alarms (RR=1·2, CI95 per cent: 0·9–1·6), or for the rate of alarms per 100 surgeon-hours (RR=1·0; CI95 per cent: 0·8–1·4).

Double gloving should always be used. Contact detectors could help surgical barriers testing.

Possibilities of surgically solving the ischemic necroses of the skin and/or muscles of the forearm

Al.V. Georgescu, O. Ivan, C. Maior and R. Onoe *Clinic of Plastic Reconstructive Surgery, University of Medicine 'Iuliu Hatieganu' Spitalul Clinic de Recuperare, 3400 Cluj-Napoca, Str. Viilor Nr. 46–50, Romania*

General approach: As a direct consequence of a trauma or of an incomplete and/or incorrect approach in emergency, the necroses may compromise the injured segment of the limb generating major morphological and functional problems. As for the surgical treatment applied, it varies from simple excision and covering (usually enough for skin necroses) to complex surgical procedures (the deep necroses, affecting muscles of the limb).

Material and methods: There are cases from two categories: a) wide skin necroses in which, due to the exposure of bone, vessels, nerve and tendons, it was necessary to use fasciocutaneous or musculocutaneous free flaps in order to cover the existing defects; b) necroses of the anterior compartment musculature, requesting flexors' reconstruction by musculocutaneous nerve supplied flaps.

A special case was that of a mangling trauma resulting in an association of crush and burn, causing both skin and muscles necroses; in order to solve this case we performed two simultaneous microsurgical free transfers: a fasciocutaneous flap and a nerve supplied musculocutaneous flap.

Results: We confronted good progress of all treated patients: a) complete good quality integration of the fasciocutaneous flaps; b) sufficient functional recovery for the musculocutaneous flaps, helping the patient to socially and professionally reintegrate.

Conclusions: 1) The correct first approach in emergency avoids problems such as ischemia. 2) Once these problems occurred there is only one solution of excision, fasciotomy and covering of the defects. 3) We consider that the best option for the skin-only defects would be the fasciocutaneous flaps and for the muscle defects requiring functional recovery the use of nerve supplied muscle flaps is needed.

Laparoscopic pericystectomy with the harmonic scalpel for hepatic hydatidosis: case report

A. Alper, I. Özden, O. Bilge, Y. Tekant, L. Avtan, K. Acarli, A. Emre and O. Ariogul *Istanbul Faculty of Medicine, Hepatopancreato-biliary Surgery Unit, 34390 Capa, Turkey*

In this videoband, we present a case of hepatic hydatidosis treated by pericystectomy with the aid of the 'harmonic scalpel' apparatus (Ethicon).

The patient was a 47-year-old man with a computerized tomography revealed Gharbi grade III exophytic lesion (8 × 6 cm) at segment III. At the laparoscopic exploration, the cyst was found to be covered with omental adhesions which were divided with the aid of 'harmonic shears'. The cyst was removed by cutting in the plane between the cyst and hepatic paranchyma in the coagulation mode of the apparatus at full energy. Two hepatic ven branches (1–1·5 mm) and an arterial branch (1 mm) were observed as disting structures and secured with clips. At the end of the procedure, there was only minimal bleeding from the liver surface and this was controlled with the argon beam coagulator. Then the cyst was placed into a plastic bag and extracted after the cyst contents were partially removed. The postoperative course of the patient was uneventful. He was discharged after two days.

The harmonic scalpel greatly facilitates the procedure by sealing the 'raw' liver surface effectively, i.e. there was no leakage of bile and only minimal bleeding. With the aid of 'harmonic scalpel' or a similar apparatus, pericystectomy can be conveniently added to the armementarium of the laparoscopic surgeon. This operation should be performed in the institutions with extensive experience in both laparoscopic and hepatobiliary surgery.

Hydatid disease. Location, complications, diagnosis, and treatment. Social and economic importance

L.D. Atanassov and G.N. Gelov *Regional Hospital, Surgical clinic, Haskovo, Bulgaria*

Introduction: The hydatid disease is a zooanthroporosic parasitosis – a wide-spread ailment. It was first described in 1821 by M. Bremser. Liver is infected most often but the disease can also develop in other organs of the human body.

Methods: We discuss 87 cases with hydatid cysts located at different places in the body treated at our clinic during the period 1993–1997. We also discuss the study of approximately 15 per cent of the homeless dogs for bearing the parasite and the study of 100 random chosen vegetable samples from the green market for the eggs of the parasite.

Results and discussion: The operated patients are: 34 (39·08 per cent) males and 53 (60·92 per cent) females, aged from 15 to 80 years.

To diagnose the disease we used – clinic examination: 87 cases (100 per cent); rentgenography: 87 cases (100 per cent); angiography: 13 (14·94 per cent); CT: 34 (39·08 per cent); sonography: 87 (100 per cent); serological samples: 81 (93·10 per cent).

Complications before the operation were discovered in nine cases (10·34 per cent) – biliary peritonitis: 2 cases; broncho pleural fistula: 1 case; suppuration of the cyst: 2 cases; icterus: 1 case; cyst perforation: 3 cases.

80 (91·95 per cent) of the operated patients were completely cured. Seven (0·05%) of the cases developed new cysts of the liver after the first year of the operation.

The postoperative complications: infiltrations of the operative wounds infestation, suppurations, prolonged drainage. Fistulizations were discovered after the first month since the operation. Recurrences were discovered during the course of the first year after the operation.

79 (90·80 per cent) of the operated patients were traced. They did not show any consequences of the disease.

The average stay of the patients in the clinic is 15·4 days.

The average time for recovery and restart of work activities is 84·3 days. The average losses of working time for the enterprise is 100 working days.

In 45 per cent of the approximately 15 per cent of the examined homeless dogs the parasite was found.

Six per cent of the vegetable samples were also infected with the parasite eggs.

Conclusions: The applied methods of treatment of the solitary form of the hydatid disease are appropriate for its complete curing. The postoperative complications vanish during the first month after the operation. Recurrent cyst develop during the first year.

The problem – homeless dogs – hydatid disease – was placed on the agenda of the medical, veterinary and town authorities as one of vital social importance and significant consequences.

Left hepatectomy in cirrhotic liver using the harmonic scalpel

A. Celdrán, O. Frieyro, J.L. Souto, A. Franco, D. Huerga, E. Bernal and R. González-Cajigal *Departments of Surgery and Radiology, Clinica 'Nuestra Señora de la Concepción', Fundación Jiménez Diaz, Avda. Reyes Católicos, 2 28040, Madrid, Spain*

Introduction: Bleeding is an important drawback during liver resection in patients with cirrhosis. The harmonic scalpel, an ultrasonically activated scalpel introduced by Amaral in 1993[1], could represent an improvement with respect to surgical cutting and coagulating during hepatic resection in this type of patient. We present a II-III segmentectomy for hepatocellular carcinoma in a cirrhotic patient using this recently introduced device.

Case report: A 72 year old man with a Child A liver cirrhosis, related to hepatitis C virus, with a 2 cm nodule in segment III, closed to right hepatic vein, has been operated on through a bilateral subcostal laparotomy. Intraoperative ultrasound did not find other nodules in the rest of liver parenchyma. Resection was performed with intermittent Pringle maneuver with complete occlusion during 15 minutes followed by 5 minutes of rest. Blood transfusion was not required. Ascites appeared during postoperative period was controlled with diuretic treatment.

[1] Amaral J.F., The experimental development of an ultrasonically activated scalpel for laparoscopic use. *Surg. Endosc. Laparoscopy* 4: 92–9, 1994.

Surgical treatment of achalasia by laparoscopy

J. Vazquez Echarri, J.M. Romeo, C. Montes, M.L. Ares, A. Marinelli, J. Martin Benito, M. Salvador, E. Gonzalez and J.L. Martinez Veiga *Serv. de Cirugía General y Digestiva, Hospital 'Severo Ochoa', Avd. de Orellana s/n, Leganes, 28911 Madrid, Spain*

Introduction: In spite of the fact that pneumatic dilation of the cardia in achalasia offers some acceptable results, dysphagia, although diminished, usually reappears during the first months. We show a Heller myotomy associated with a Dor fundoplication in an achalasia patient, sent directly to surgery without previous dilation. The patient complained for year and half of progressive dysphagia and regurgitation, having lost 6 kg of weight. The X-ray study, endoscopy and manometry were compatible with achalasia, with tendency towards vigorous type and LESP at rest of 36 mmHg.

Material and methods: Five trocars of 10 mm were used, placed in right midclavicular line, left anterior axillary line, left middle clavicular line, subxyphoyd and upper middle line where the optics of 0° was placed. We carried out the complete dissection of the esophagic hiatus. Once dissected both crura, the esophagus was isolated creating a posterior window from right to left, surrounding it with a ribbon. At least about 7 cm of esophagus was freed identifying and peserving the anterior vagus. The myotomy was carried out with scissors without electrocoagulation and maintaining an intraesophageal bougie of 40F, beginning 2 cm below the gastroesophageal junction. We used the cardial artery like anatomical reference. The myotomy was prolonged upwards in about 6 cm being testing by intraoperative endoscopy its completion and the absence of perforation. We performed a partial fundoplication Dor type to avoid the gastroesophageal reflux.

Conclusion: The postoperative evolution was satisfactory. After one year the patient is totally asymptomatic without dysphagia, nor pyrosis. The manometry show a high pressure zone of 3 cm of length with 8 mmHg and a pHmetry without pathologic reflux.

Subtotal left hepatic lobectomy

C. Di Martino, P. Celestre, A. Conti, N. Caruso, M. Iacampo, A. Civitella and F. Cristini *Divisione di Chirurgia, Ospedale di Colleferro, 00034 Colleferro, Rome, Italy*

The principle of hepatic resections is founded on the plurisegmental anatomy of the liver. According to Couinaud's classification, left hepatic lobectomy corresponds to the removal of the II and III segments. In order to perform a guided resection, it is necessary to divide the left supra-hepatic vein in correspondence of its outflow into the caval vein or into the middle supra-hepatic vein. Obviously, it is also necessary to interrupt the biliary, portal and arterial branches of the hepatic pedicle in connection to such segments. The crucial point of the operation is undoubtedly represented by the identification and ligature of the left supra-hepatic vein on the right site of its outflow. In fact, it may drain directly into the caval vein, as well as into the middle supra-hepatic vein. Since a correct intraparenchymal identification of the left supra-hepatic vein is considered mandatory, in order to avoid complications, such as dangerous hemorrhages, due to caval lesions, or accidental ligature of the middle-supra-hepatic vein. In some cases, where a total left lobectomy is not considered essential to the aims of the operation, it may be performed a left subtotal lobectomy, in which the ventral branch of division of the left-supra-hepatic vein is preserved and used as a guide to identify the dorsal branch, which may be easily divided. By the way, any complication of severe hemorrhage or accidental ligature of the middle supra-hepatic vein is highly reduced. The authors show the fundamental stages of the intervention of subtotal left hepatic lobectomy, performed in a female 53 year old patient, due to the presence of a large suppurated cyst of the left hepatic lobe in association to a pseudo-inflammatory hepatic tumour.

Traumatic rupture of the trachea and esophagus solved by primary suture

S. Haruštiak, R. Benej, A. Pereszlenyi jr. and Š. Bohucký
National TB and Respiratory Diseases Institute, Bratislava, Podun, Biskupice, Slovakia

Authors present an unusual case of complete traumatic rupture of the neck part of trachea with almost complete rupture of esophagus. In spite of more than 48 hours time delay since injury, they decided to perform a primary reconstruction of trachea and esophagus. They describe an original way of reconstruction of trachea with a T-type silicone tube in a presence of dilaceration of trachea and fracture of the arch of cricoid cartilage. In spite of a complete rupture of trachea with dilaceration and with distraction of parts of trachea they achieved a perfect reconstruction with the vocal function remaining.

Video-assisted thoracoscopic lung biopsy – the new diagnostic procedure in case of disseminated pulmonary diseases

L. Kecskés, Á. Füredi and P. Gehér *Markusovszky Teaching Hospital, 9700 Hungary Szombathely, Markusovszky str. 3*

Sometimes patients have more than one organ or system affected by infections or neoplasia or other diseases, requiring quick and precise diagnostic investigation. In these situations, different invasive diagnostic procedures may be necessary. Open, or nowadays video-assisted lung biopsy is required to clarify the pulmonary diagnosis. The new method has been used in our department from May of 1994. We have performed 35 VA(S-k)assen biopsy (male: 18, female: 17). Mean age 48·3 (26–67) years. In two cases we had to make a conversion. There were no severe complications and mortality. Most patients had pulmonary fibrosis and sarcoidosis. We conclude, that video-assisted thoracoscopic technique of lung biopsy is simple, useful, and safe.

Wide-en-bloc resection of giant right adrenal tumour

C. Di Martino, P. Celestre, A. Conti, N. Caruso, M. Iacampo, A. Civitella and F. Cristini *Divisione di Chirurgia, Ospedale di Colleferro, 00034 Colleferro, Rome, Italy*

Interventions of wide-en-bloc resections of adrenal tumours involving adjacent organs have been reported. They may include nephrectomy, splenectomy, hepatic, pancreatic, intestinal resections according to the extension of the tumour and the degree of infiltration of the peritumoral organs. The authors report the case of a 63-year old female patient undergone wide-en-bloc resection of a giant right adrenal tumour, including right nephrectomy. CT scan showed the presence of a retroperitoneal mass, 13×18 cm, extending itself from the diaphragm, with compression of the right lobe of the liver, down to the posterior wall of the right kidney, which appeared dislocated in an anterior plane together with the caval vein. The principal stages of the operation were: 1) Right thoracophrenolaparotomy. 2) Adequate mobilization of the liver by incision of its round, suspensor, triangular and coronary ligaments. 3) Preparation of the suprahepatic caval vein in order to clamp it in case of necessity. 4) Preparation of the retro-hepatic and subhepatic caval vein with isolation of both renal veins. 5) Isolation of the right ureter. 6) Mobilization of the tumoral mass, deeply located in the retroperitonal space, by freeing it from the posterior plane. 7) Wide-en-bloc resection of the tumour including right nephrectomy. The authors stress the necessity of accurate preparation of the caval vein before any attempt to remove the adrenal tumour, because of possible dangerous intraoperative hemorrhage, due to accidental laceration of adrenal veins.

Near total thyroidectomy

C. Di Martino, P. Celestre, A. Conti, M. Iacampo, N. Caruso, A. Civitella and F. Cristini *Divisione di Chirurgia, Ospedale di Colleferro 00034, Colleferro, Rome, Italy*

Surgical removal of the thyroid gland may be complete, as in total thyroidectomy, or incomplete. In the last case, it may be a subtotal thyroidectomy, where it is presumed that the residual tissue may be sufficient to maintain the hormonal function, and a 'near total' thyroidectomy, where the remaining tissue is so minimal not be be sufficient to guarantee any functional activity. Thereby, the 'near total' thyroidectomy is functionally compared to a total thyroidectomy. The choice of this procedure is strictly connected to technical reasons, in order to avoid the possible complications commonly reported in a total thyroidectomy. These are represented by an increased rate of damage to the parathyroid glands, with the effect of a permanent postoperative hypoparathyroidism, as well as by lesions to the recurrent nerves. The authors describe the technique used in performing a 'near total thyroidectomy', with particular regard to the principal stages of the intervention that may favour the preservation of the parathyroid glands as well as of the recurrent nerves. These principally consist in: 1) a preservation of a small pretracheal fibrotic lamina in correspondence of the superior pole of the thyroid, where the recurrent nerve strictly adheres to the thyroid capsule. 2) a lower ligature of the superior thyroid artery comprising a minimal quantity of glandular parenchyma. The reason for it is that of offering a better vascularization of the superior parathyroid glands, by preserving the posterior thyroid vessels, as well as that of avoiding their accidental removal.

The percutaneous treatment of the thyroid gland's cysts

A. Zubov *Donetsk Diagnostic Center, Illych av., 14, 340099, Donetsk, Ukraine*

Purpose: To evaluate the efficiency of the percutaneous treatment of the thyroid glands cysts of various causes under the sonographic control.
Materials and methods: Since 1991 to 1996 the percutaneous treatment of the thyroid gland's cysts was used in 293 patients. The majority of them (90 per cent) were women. The localization of the cysts was, as a rule, in right or left lobes in equal frequency, rather seldom – in the isthmus. The diameter of cysts was from 5 mm to 80 mm. The selection of a secure approach to the cysts was carried out under the sonographic control. We used 7·5 MHz-transducer. The color Doppler device was used in order to avoid both the gland and vessel damage. A fine-needle puncture of the thyroid gland was performed with aspiration of the content of a cyst after detecting the secure approach. The etiology of cysts was, as a rule (67 per cent), the hemorrhage in the thyroid parenchyma or the destruction of adenoma-like node, which had been confirmed by cytologic investigation of the aspirated material. The frequency of so-called 'virtual' cysts was 25 per cent. The features of virtuality are: distinct capsulae, the transparent content and the typical elements of a cyst's internal cover. In such cases sclerotherapy by injection of the 96 per cent ethyl-alcohol was carried out after the aspiration. The amount of alcohol to be injected was 60 per cent of the cyst's volume. The cytologic investigation revealed malignant cysts in 6 per cent of all cases.
Results: Good further results are obtained in 60 per cent of cases: the absence of residual cyst 12 months after the percutaneous aspiration. In cases of a sclerotherapy no residual cyst was revealed in 12 months after the treatment. 20 per cent of the patients with residual cysts have undergone additional percutaneous aspirations with good results. The remaining 20 per cent of the patients were operated because additional aspirations had been resultless.
Conclusion: The percutaneous aspiration of the cysts of the thyroid gland under the sonographic control is minimally-traumatic, efficient and profitable method of the treatment.

Laser photocoagulation of thyroid neoplasms

A. Zubov, Y. Chyrkov, M. Stryuk, P. Paniotov and O. Senchenko *Donetsk Diagnostic Center, Illych av., 14, 340099 Donetsk, Ukraine*

Purpose: To study the efficiency of ND-YAG laser treatment, in the regime of the interstitial therapy, of both thyroid nodes and residual cysts after the aspiration. To find out an optimal possible regime of the photocoagulation using the light-conductor which has the sideradiation, and using the ITT-light-conductor.
Materials and methods: The photocoagulation was performed after percutaneous puncture of the thyroid neoplasm. The ND-YAG-Fibertom laser, the empty-light-conductors and the ITT-light conductors were used. The light-conductor was led to the zone of interest through the lumen of a punction needle under sonographic control. Three seances of photocoagulation of nodes, 10–15 mm diameter, were performed, as well as two seances with nude fiber, power 10 wt and 3 sec-exposure. One seance of ITT-light-conductor therapy, power 5 wt with exposure 20 sec was performed. The laser photocoagulation of the walls of cysts was performed after the aspiration of its contents in four patients. The diameter of cysts was from 20 to 40 mm. The nude light-conductor was used, the radiation power was 10 wt, the exposure was 6 sec. The hyper-echo zone, connected with gas artifacts and obstacling the correct visualization, was detected in all cases of the sonographic control.
Results: No one complication was revealed. The hyper-echo zones in the points of laser treatment were detected one year after the photocoagulation. Both cysts and nodes recidives, as well as far-time complications after therapy were not revealed.
Conclusion: So, the interstitial laser thermotherapy is both efficient and efficient and safe method of the treatment of thyroid diseases, accompanied with the cysts and nodes. Further elaborating and amendment of this prospect method will allow to broaden the area of its use.

Laparoscopic versus mini-laparotomy approach for lumbar sympathectomy

Á. Balogh, Zs. Palásthy, R. Sipka and P. Vattay *Albert Szent-Györgyi Medical University Department of Surgery, P.O. Box 464, H-6701, Szeged, Hungary*

A total of 20 patients with severe lower leg ischaemia (Fontaine III. st.) caused by popliteocrural arterial occlusion underwent lumbar sympathectomy in general anaesthesia. It was the aim of this study to develop a minimal invasive approach for this procedure, with less invasivity and shorter operating time than the traditional translumbar gridiron incision. Patients have been randomly selected in two groups. In group I (10 patients) we applied laparoscopic retroperitoneal approach, with insufflation using three ports, and normal laparoscopic instrumentarium. In group II (10 patients), we performed a 3 cm long minilaparotomy incision with gridiron lumbar transmuscular approach using the 'Rozsos' device, a specially developed lighting retractor system. We considered the procedure a successful one if the intervention could be performed within half an hour and without any intraoperative complication. The operation was converted for the traditional open gridiron incision when it could not be accomplished within 30 minutes. Group I: except one all laparoscopic attempts have to be converted success rate 1/9, three minor complications occurred. Group II: all the 10 procedures have been completed within 8–14 minutes, only one complication occurred, and the hospitalization was 2–4 postoperative days. Following this randomized clinical study, we performed further 27 lumbar sympathectomies from minimal invasive direct access using the 'Rozsos' retractors, with the same satisfactory result.

It is our conclusion that the mini-laparotomy approach for lumbar sympathectomy with 'Rozsos' retractor system is superior to the traditional translumbar open, or laparoscopic approach in regard to operation time, invasivity, complication rate and recovery.

Reconstruction of a bilateral congenital renal artery stenosis

Cs. Dzsinich, Gy. Sepa, G. Biró, M. Százados and K. Hüttl
Department of Cardiovascular Surgery of Semmelweis Medical University, Városmajor u. 68, H-1122 Budapest, Hungary

This video presentation shows a surgical procedure in case of a bilateral congenital renal artery stenosis. This 16-year old girl had severe hypertension since her early childhood which worsened since she became adolescent. The maximum value of blood pressure was 190 over 140 mm of mercury. She required combined medication of four anti-hypertensive drugs. No sign of renal insufficiency could be obtained. DSA renal angiography revealed high grade bilateral renal artery stenosis with post-stenotic dilatation at the orifices typical for congenital origin. There was no evidence of any specific inflammatory disease like Takayasu's arteritis.

During surgery the renal arteries were approached through a midline incision. The retroperitoneal space was entered paraduodenally and the renal arteries were prepared for clamping. Patient was anticoagulated and both renal arteries were ligated. Transection of the dilated parts was followed by direct reimplantation into the aorta with continuous suture. The entire clamping time was 24 minutes. After having released circulation diuresis started. Anticoagulation was reversed and the wound was closed over suction drain. The postoperative course was uneventful. Blood pressure returned to normal. The patient was discharged at the 7th postoperative day and required salicylate medication only.

Conclusion: Congenital renal artery stenosis – those are not suitable for dilatation – can be treated by surgery. Direct replantation can be done with low ischemic risk and provides good results at long run.

The use of the fasciocutaneous forearm free flap as a cutaneous and vascular graft

Al.V. Georgescu, O. Ivan, R. Onoe, S. Serbu and C. Melincovici
Clinic of Plastic Reconstructive Surgery, University of Medicine 'Iuliu Hatieganu', Spitalul Clinic de Recuperare, 3400 Cluj-Napoca, Str. Viilor Nr. 46–50, Romania

General approach: In certain casualties, the amputation (either complete or partial) occurs associated to large soft tissue losses. In such casualties, for treating the tissue losses, we very much shorten the bone segments – sometimes even an entire segment of the limb. One of the alternatives for such casualties is the free microsurgical transfer of a fasciocutaneous flap having its skin elements used for covering the soft tissue losses and its vessel pedicle used as a vessel graft for the blood supply of the amputated limb.

Material and method: There are here presented some casualties with partial or complete amputation of the forearm and of the calf.

In both situations – with large soft tissue losses — we used a fasciocutaneous radial forearm free flap using its skin component for covering the defects and its vessel pedicle as a vessel graft in order to re-achieve the blood supply of the area.

Results: The flaps had a perfect integration resulting in a good covering as well as good viability of the amputated segments.

Therefore, in order to avoid the excessive shortening of amputated limb segments, the use of fasciocutaneous free flaps with double role appears as an important method of treatment.

Haemorroidectomy – Ferguson Technique with diathermic dissection

P. Costa, H Moreira, C. Mexedo, V. Mendes and C. Oliveira
Serviço de Cirurgia 3, Hospital de S. João, 4200, Porto, Portugal

Aim of the study: The aim of this video is to demonstrate the technique of Ferguson haemorrhoidectomy with diathermic dissection
Materials and methods: Use of a disposable enema two hours before the operation Patient in prone jackknife position Posterior perineal block with bupivacaine for control of postoperative pain Rectal exam and definition of the piles and skin bridges. Entire dissection of the piles with diathermy indentifying and sparing the internal anal sphincter Ligation of the narrow pedicle of the dissected pile with 2/0 cromic and closure of the mucosa and anoderm, without tension, with a running suture.
Summary of results: We didn't find intense postoperative pain, and bleeding, sepsis or anal stenosis
Conclusions: The Ferguson technique with diathermic dissection showed to be a safe procedure with good results with less bleeding than the classic techniques

Endoscopic transrectal resection of rectalvillous tumours using an urologic resectoscope

J.P. Arnaud, Ch. Cervi, J.J. Tuech, C. Casa and R. Bergamaschi
C.H.U., Angers, 4 rue Larrey, Angers 49100, France

Introduction: The use of a 'rectum resector' similar to a cystoscope was reported in treatment of villous tumours of the rectum.
Technique: The patient is placed in the dorsal lithotomy position; the standard urologic resectoscope is then inserted into the rectum using the obturator. After the instrument is placed under vision through the lesion, the resection is begun in much the same manner as a transuretheral resection of the prostate. The tumour is resected flat to the adjacent normal rectal wall. Resection is carried out circumferentially around the lumen until all tumour is removed. The irrigant carries the chips and blood into the colon and allows excellent visualization without anal dilatation. A few chips are gathered for pathologic examination.
Patients and results: This technique has been performed in 20 patients, with a mean age of 74 years, presenting a rectal villous tumour. No mortality or morbidity were observed. The average operative time was 35 minutes and the average hospital stay was four days. There was only one recurrence treated by laser at follow-up ranging 14 to 48 months.
Conclusion: This endoscopic procedure is safe, nonexpensive, easily available and does not require anaesthesia; it seems to offer adequate surgery in rectal villous tumours.

Colo-dentate line anastomosis for low rectal cancer

P. Chiotasso *Department of general and digestive surgery, pavillon Dieulafoy, CHU Purpan, Baylac, 31059 Toulouse, France*

The aim of the video is to describe the particularities of a low anterior rectal resection for a cancer situated at 4 cm from the anal verge, considering both the oncological and the functional aspects. Several technical comments are proposed:

- The lower tumour level must be at least 4 cm from the anal verge, in order to have the usual 2 cm free margin below; if not, the anal canal under the dentate line would be resected and the anal continence would be compromized.
- A total mesorectum resection is performed, the dissection being done in the avascular space. All the lymph nodes from the inferior mesenteric artery territory are resected: for this reason, this technique is probably better than a local excision, taking into account the risk of early lymph node invasion of a small rectal cancer. This technique has also the advantage to widely excavate the pelvic cavity and thus facilitate the low mobilization of the rectum, particularly for a narrow pelvis in a man.
- Only supposed low Dukes' A cancers are eligible for this kind of conservative resection, the half upper part of the internal sphincter being resected just upper the dentate line. If the tumour invades the perirectal tissues (Dukes B) at this level, it would be necessary to resect a part of the pelvic floor to obtain a lateral free margin: thus, a Miles' procedure would be necessary.
- In this technique, the colo-dentate line anastomosis cannot be performed with a stapler: it would destroy the remaining lower part of the anal canal under the dentate line. The anastomosis is routinely performed through the anal canal using a hand suture. A diverting loop colostomy is performed to prevent the risk of fistulae.
- Six patients were operated using this technique between February 1994 and June 1997. All were Dukes' A except one with early lymph nodes invasion in the mesorectum. No patient had preoperative pelvic irradiation except one. During the first postoperative months, the functional results were poor: incontinence, multiple daily bowel movements. However, the results improved spontaneously during the first year. At this time, no patient presents sign of recurrence.

In conclusion, the colo-dentate line anastomosis seems a good alternative to a local excision or a Miles' procedure for a low rectal cancer, supposed it will be a Dukes' A tumour: it allows a low resection while the usual carcinologic rules are respected.

Abdomino-transsphincteric resection of the rectum for distal rectal cancer

G. István, S. Kiss, I. Sugár, P. Ondrejka, I. Berki, G. Bognár and J. Faller *Semmelweis University, School of Medicine and Szt. János Hospital Department of Surgery, Kútvölgyi u. 4., H-1125, Budapest, Hungary*

Sphincter-saving resection for cancer of the distal third of the rectum is performed in increasing percentage of the cases. From 01.01.1994 to 31.12.1996, 43 patients were operated on for cancer of the distal third of the rectum. The rate of sphincter-saving resections was 62·8 per cent (27 cases). In 13 cases the abdomino-transsphincteric resection, as described by Lazorthes, was used.

The aim of this video is to present this technique.

The patient is placed in the right lateral position, with the left leg elevated to permit the simultaneous exposure of the abdomen and perineum. The laparotomy is made by a curved incision in the left inferior quadrant. After high ligation of the inferior mesenteric vessels and full mobilization of the splenic flexure, the dissection is carried down as low as possible in the pelvis.

A second incision from the sacrum to the anus is made, de coccyx is excised, the levator muscles and the external sphincters are divided in the midline. The dissection of the distal rectum and anal canal is completed. The previously divided sigmoid colon is pulled in the perineal wound and the resection is performed leaving a safe distance below the tumour. The whole mesorectum is excised. The anastomosis is performed either by hand suture or double stapling technique. The sphincter and levator muscles are then reconstructed. A diverting colostomy is applied for 6 to 8 weeks.

The abdomino-transsphincteric resection is an excellent possibility to further improve the rate of sphincter preservation in cancers of the distal third of the rectum. It is especially useful in cases with narrow pelvis or bulky tumour, in which an anterior resection is not always possible.

A new method of creation of an artificial anal sphincter with use of pedunculated muscle of the small intestine

P. Lampe, J. Slota, Z. Górka and P. Drenda *Department of Digestive Surgery, Silesian Academy of Medicine, 40-752 Katowice, 14 Medyków St., Poland*

The authors present their own method for the formation of a pseudosphincter for a faecal fistula. The pseudosphincter is formed of a pedunculated seromuscular flap of the small intestine. The method of pseudosphincter formation was used in 30 patients undergoing the abdominoperineal amputation of the rectum. The patients presented with advanced stages of rectal cancer (B and C according to the Dukes Scale). Abdominal stoma with a pseudosphincter was formed in 17 patients; in the remaining 13 patients the pseudosphincter was formed in the perineum. There was no perioperative mortality. Ultrasound scan, manometry and clinical assessment proved appropriate functioning of pseudosphincters. We believe that pseudosphincter formation with a pedunculated seromuscular flap of the small intestine can be recommended as an alternative means of preventing uncontrolled stool loss through a faecal fistula.

Staplers in colorectal oncosurgery. Modified operative technique

Iv. Mantchev, Tch. Atanassov and B. Sakakushev *Department of General Surgery, Institute of Medicine Plovdiv, Peshtersko Shosse Blv. No 7, Plovdiv, 4002, Bulgaria*

For a five year period (1993–1997) 406 operations for colorectal cancer have been done in the Department of General Surgery, 103 of which ned by 'Autosuture' staplers. From the total of 55 cases of anterior resections, 36 were low anterior resections – down to 3 cm from the anal verge.

The advantages of stapler colorectal oncosurgery techniques are outlined: safety, lesser risk of postoperative suppurative complications, time saving and greater possibility for low anterior rectal resections.

The authors describe and demonstrate on video original modification of established operative technique for colonic anastomosis, using only two GIA staplers.

Creation of the arterio-venous fistula for hemodialysis using transposed basilic vein on the arm

A. Kapala, W. Szczesny, W. Hryncewicz and Z. Mackiewicz
The Ludwik Rydygier Medical University in Bydgoszcz,
Department of General and Vascular Surgery, ul. M.
Sklodowskiej-Curie 9, 85-094 Bydgoszcz, Poland

The film demonstrates technical details of a-v fistula creation.

In the cases of irreparable failure or impossibility of performing AVF on the forearm, profitable alternative is the basilic vein on the arm.We find it through incision just below the elbow. After cutting it at this level, we ligate distal end and prepare vein from surrounding tissue. Collaterals are meticulously ligated. The incision is prolonged to the axilla. Next we rinse vein with the heparinized saline, enlarging it this way. The wound is sutured. Through another incision at the elbow level we prepare the brachial artery. Using special curved device (tuneller) we place basilic vein subcutaneously on antero-lateral surface of the arm. The vein is anastomosed with the artery end to side with vascular sutures 6–0. Thrill confirms good work of fistula. Suturing of the wounds ends operation.

Autogenous vein is an excellent material for AVF. The risk of infection is very low. Only one anastomosis is needed. The fistula is easy to inject and the blood flow is over 300 ml/min. We performed 45 fistulas that way and the patency rate is 80 per cent and 70 per cent after one and two years, respectively.

Creation of the A-V fistula for hemodialysis using PTFE graft on the arm

A. Kapala, W. Szczesny, W. Hryncewicz and Z. Mackiewicz
The Ludwik Rydygier Medical University in Bydgoszcz,
Department of General and Vascular Surgery, ul. M.
Sklodowskiej-Curie 9, 85-094 Bydgoszcz, Poland

The film demonstrates technical details of arterio-venous fistula (AVF) creation.

In cases where autogenous material is completely exhausted or unsuitable for AVF we use PTFE tapered prosthesis. First incision is made in axilla to expose axillary vein. Collaterals are ligated. The second incision is performed on elbow level. Here we prepare the brachial artery. Both artery and vein are clamped. Using special curved device (tuneller) we make subcutaneous tunnel on antero-lateral surface of the arm. Prosthesis is placed in the tunnel. Two vascular anastomosis are made (end to side) between prosthesis, artery and vein. Arterial anastomosis is 4–5 mm and venous 6–8 mm length. Clamps are removed and the fistula is ready. Thrill confirms proper work. Skin suturing ends operation.

PTFE prosthesis is very good solution for patients with poor veins. Blood flow is over 300 ml/min. It is easy to perform and puncture. If it is made aseptically, the risk of infection is relatively low. Patency rate in 30 cases is 70 per cent and 60 per cent after one and two years, respectively.

Facial palsy – long term experience with modified McLaughlin's and Gillies technique

K. Exner and G. Lemperle *St. Markus-Hospital, Clinic of Plastic and Reconstructive Surgery, D-60431 Frankfurt am Main, Wilhelm-Epstein-Straße 2, Germany*

The patterns of facial palsy vary in the degree of involvement and duration. A complete assessment of the neural and muscular status is necessary in patients presenting with partial, segmental, or complete paralysis. No single surgical technique can accomplish the most important goals of rehabilitation of the complete paralysis, which should be a normal appearance at rest and symmetry with voluntary and involuntary motion. When direct nerve suture, autogenous nerve grafting, and nerve crossover are inapplicable in the rehabilitation of the paralyzed face, dynamic support using the temporal muscle is a proven reconstructive technique. This method enables complete lid closure and active movement of the lips and cheeks, therefore improving speech.

Since 1972, we have performed a modification of McLaughlin's technique attaching a fascialata strip through the separated coronoid process and suturing this to the nasolabial fold and the orbicularis oris muscle in the midlines of the upper and lower lips. At the same time restoration of lagophthalmus is done by transposition of a temporal muscle segment, enlarged by his own fascia as described by Gillies.

The most important factor of this procedure is the obtaining of satisfactory movements by overcorrection and immediate postoperative training. Advantages of this method are an excellent appearance at rest and good symmetry with voluntary motion, ocular sphincter control and no loss of other significant functions. This one step procedure achieves an immediate facial rehabilitation.

The results of our series of 132 patients with a median follow up of 9·7 years demonstrate the possibilities of this technique. The average degree of reanimation in the nasolabial fold is 6·8 mm (range 4–16 mm). A complete lid closure was obtained in 87 per cent. The rewarding improvements in the psychological sequels emphasize the value of this method especially in chronic cases of complete facial paralysis in the elderly patient.

Unusual form and localization of the hydatid disease

M. Ristov, E. Mitev, T. Porjazoski, M. Hadzi-Mancev *Surgical Department, Medical Center Stip, Republic of Macedonia*

Primary retroperitoneal hydatid cyst without involvement of another peritoneal organ is extremely rare, especially alveolar form of the hydatid disease.

Case report: A 62-year old woman with a six month history of pain in right hypochondrium and right lumbar fossa was referred to us. Ultrasonographic examination of the abdomen revealed a cystic lesion lying in the right hypochondrium, near the right kidney – suspected hydatid cyst. Laboratory findings and chest X-ray examination were normal. Immunological test, complement fixation was positive.

At exploratory laparotomy abdominal contents were normal. After incision of the posterior peritoneum we found a large cyst with multivesicular infiltrative structures – alveolar form of the hydatid disease.

The treatment of the cyst was by evacuation of the cyst contents and reduction of the cyst. We used hypertonic saline and finally we drained this space with two drains. Postoperative period was normal. Albendazole adjuvant chemotherapy was given to the patient three months.

Comment: Echinococcus multilocularis cause alveolar hydatid disease. The probable mode of spread of the hydatid embrio to the retroperitoneal space is either via the lymphatic from the gastrointestinal tract or via the portal system of the liver.

In the period of the last 15 years in our department were operated 98 cases with hydatid disease, and all of them were cystic form of the hydatid disease. This case was only retroperitoneal one in the series. The hydatid disease a fairly common disease can become very difficult and even impossible to diagnose. The most important factor in diagnosing hydatid disease is the awareness of its possibility.

Different localizations of the hydatid disease

M. Ristov, E. Mitev, T. Porjazoski and M. Hadzi-Mancev
Surgical Department, Medical Center STIP, Republic of Macedonia

Introduction: Hydatid disease remains a big problem for the patient and surgeon especially when it affects multiple sites, which need different surgical treatment. The authors present a rare case of the patient with four distinct sites of echinococcus cysts which were treated in the period of two years.

Materials and methods: A 56-year-old woman admitted to the hospital with right hypochondrial pain and palpable mass. Ultrasonography at the abdomen show the large echinococcus cyst with daughter cysts into the right lobe at the liver and a echinococcus cyst at the right ovary. Both cysts were treated at same time. After 18 months at the routine follow-up we found big echinococcus cyst at the spleen and another cyst in the pelvic cavity – secondary echinococcis.

Results: In this video presentation different methods of management of hydatid disease were presented in the same patient. Evacuation of the cyst contents, partial pericystectomy, scolicid treatment of the cyst, visualization and closure of communicating bile ducts, omentoplasty and drainage, were the method of choice at the treatment of liver hydatidosis. Primary hydatid cyst of the ovaries is very rare. The disease is usually acquired in childhood and may take from five to 20 years before it is diagnosed. The surgical treatment was removing the ovary, fallopian tubes and cyst. Echinococcus of the spleen is also very rare. In our case there was a large cyst with destruction of the spleen tissue and the only one management in this case was splenectomy. The secondary echinococcosis is possible, especially if we have had bad isolation and scolicid treatment. The treatment of the pelvic cyst was evacuation, pericystectomy and drainage.

Conclusion: The surgical treatment of the hydatid disease can be different. It depends on cyst localization and organ destruction.

Gasless operative laparoscopy: five years of experience

R. Sampietro and C. D'Urbano *Department of General Surgery and Minimally Invasive Therapy Unit, San Carlo Borromeo Hospital, Via Pio II, 3 20153 Milan, Italy*

Pneumoperitoneum is a limiting factor for Operative Laparoscopy. Rare but dramatic are the accidents linked to the 'blind' realisation. Contraindications are patients with cardiopumonary risk, politrauma with suspected or clear hemoperitoneum (hazard of gas embolism); epidural anaesthesia is also a contraindication. For these reasons, in our department, in 1993 we have started the Gasless Operative Laparoscopy Project (GOLP). The possibility to obtain an effective working chamber by mechanical elevation of the cutaneous plane brought us to carry out a mechanical arm with two steel needles an 'open celioscopy'. With this procedure we obtain a working chamber similar to the pneumoperitoneum. This device (Laparotenser), permits to use unvalved ports, to perform a minilaparotomy for operative purpose without compromission of the working chamber. This technique demonstrate to be effective, safe and economic. This method has therefore been shown to provide the following advantages: no changes in the hemodynamic and blood gas parameters; no postoperative shoulder pain; permits epidural anaesthesia; permits continuous suction without compromising the work chamber; eliminates the need for valved ports; reduces overall costs.

Our experience is the following: cholecystectomy 464; colonic resection 32; diagnostic laparoscopy 22; adhesiolysis 15; hernyorraphy 9; appendicectomy 8; duodenorraphy 4; ilel resection 3; gastroenteroanastomosis 3; foreign body ablatio 3; hepatic fracture 3; hepatic cyst fenestration 3; spermatic vein ligation 2. Total: 570.

Pancreaticojejunostomy on a separate loop after duodenopancreatectomy

E. Bratucu, D. Straja, D. Ulmeanu and M. Marincas *Caritas Hospital, Surgery Department, 29 Traian Str, 7000 Bucharest, Romania*

The pathological entities known as periampullar malignancies (duodenal malignancies, pancreatic adenocarcinoma, malignancies of the distal common bile duct, malignancies of the hepatopancreatic ampulla) represent an increasing number of dreaded diseases and became well known and quite common. They require surgical treatment: rarely intervention, often palliative procedures.

We performed in our clinic a study of 60 cases of periampular malignancies in which the standard surgical treatment was pancreaticoduodenectomy, as a radical surgical intervention. It represents the experience of our clinic in the last 30 years.

We studied the reconstructive procedures, in order to achieve a safe technique that allows the decrease of the postoperative morbidity and mortality rates. The high postoperative morbidity rate of the 'classical' reconstructive procedures is due to fistulas of the pancreaticojejunostomies – pancreatic fistulas which can become complex bilio-pancreatico alimentary fistulas.

We obtained best results using pancreaticojejunostomy on a separate jejunal loop, dissociated from the biliojejunostomy and gastrojejunostomy. We obtained a safe biliary and digestive continuous transit, and a derived pancreaticojejunal transit. In the 60 dudodenopancreatectomy done this type of reconstruction was realized in 42 cases, with a decreased morbidity and mortality rate compared to the classical methods.

Jurasz operation performed by laparoscopy

P. Hauters, C. Ngongang, P. Janssen, J. Janssen and L. Hachez *Clinique Notre-Dame, 9 Avenue Demmée, 7500 Tournai, Belgium*

Aim: The authors present a cystogastrostomy (Jurasz procedure) performed by laparoscopy.

Material and methods: The operation is performed for a pseudocyst of 6 cm of diameter persisting five months after acute pancreatitis. As demonstrated by CT scanner, the cyst is displacing anteriorly the medium part of the stomach.

The operation starts with a conventional laparoscopy. Afterwards, three trocars (one of 10 mm for the laparoscope and two of 5 mm for the various instruments) are introduced directly in the lumen of the stomach to perform the cystogastromy.

To facilitate the further introduction of the trocars in the stomach cavity, the anterior wall of the organ is anchored at the abdominal wall. The stomach is insufflated via the port of a 10 mm blunt trocar whose special design will prevent any gas leakage. The laparoscope is introduced into that trocar, a good visualization of the inside of the stomach is then obtained and the Jurasz procedure is performed. A cystography is first realised to determine the inferior part of the cyst. The cystogastrostomy is done at that level. At the end of the procedure, a nasogastric tube is left in place.

Conclusion: The postoperative evolution is uneventful. The patient is discharged from the clinic on the third day. A CT scan is performed one month postoperatively; the pseudocyst has completely disappeared.

Extended lymph node dissection during whipple procedure

D. Kelemen and Ö.P. Horváth *I. Surgical Clinic of Medical University of Pécs, Ifjuság u. 13, 7643 Pécs, Hungary*

Aim of the study: The results of pancreatoduodenectomy for the carcinoma of the pancreatic head have been disappointing. The five-year survival rate is about 10–15 per cent. Probably the insufficient lymph node clearance might be the cause of the local recurrence. For this reason some authors offer the extended lymph node dissection during Whipple procedure in order to improve the survival rate. The present video shows our first experience with this operation.

Materials and methods: We prefer the pylorus-preserving pancreatoduodenectomy, if there is no oncological contraindication of that. However this procedure was completed with regional and juxta-regional lymph node and connective tissue clearance.

Summary of results: Although the operation was longer because of the dissection, it did not result in further complication.

Conclusions: Our early experience is advantageous with this extended procedure. Although its positive effect could not be measured yet, the improvement of the survival time will be expected.

Laparoscopic pancreatic cystogastrostomy. A simplified technique

M.A. Secchi, E. Tagliaferri, L. Quadrelli and L. Rossi *Surgical Division 'B' Hospital Italiano de Rosario, Argentina*

Patient: A 69-year old caucasian female patient, admitted for electivel surgical treatment of a symptomatic pancreatic pseudocyst.

History: A conventional cholecystectomy had been performed eight years before. An ERCP with endoscopic papillotomy was made three months earlier to treat an acute pancreatitis with persistent papillary obstruction by an impacted gallstone. Ultrasound and preoperative CT scan showed a pancreatic pseudocyst (12 cm diameter) in close contact with the posterior gastric wall. Fluid content was predominant.

Procedure: Under general anaesthesia, a transumbilical videolaparoscopy was started. Three other trocars were introduced into the peritoneal cavity in a standard position to gastric surgery.

1) Anterior gastric wall was opened. 2) Cyst puncture. 3) Cyst opening by a 2 cm window. 4) A multifire Endo-GIA 30 was introduced. 5) A stappler side-to-side pancreatic cystogastrostomy was performed. 6) The cyst cavity was cleaned. 7) Anterior gastric wall was closed by a 2/0 PDS continuous suture. 8) The procedure was finished.

Postoperative control: No complications were detected.

Training for advanced laparoscopic biliary procedures using a pig model

I. Gál, Z. Szabó, G. Csáky** and Gy. Wéber*** *Department of Surgery Bugát Pál Hospital, Gyöngyös, M.O.E.T. Institute San Francisco, USA; **Department of Surgery County Hospital, Miskolc; ***1st Department of Surgery University Medical School of Pécs, Hungary

Although perioperative endoscopic retrograde cholangiopancreatography may be a preferred method for handling common bile duct stones in the laparoscopic era, laparoscopic common bile duct (CBD) exploration is also being promoted. Surgeons who have gained experience and confidence with laparoscopic cholecystectomy are now applying the minimally invasive approach to other biliary procedures such as common bile duct stones and obstructive jaundice.

Our eight minute video demonstration shows a prepared pig model, by which one can acquire experience for the technique of laparoscopic CBD exploration. The small size of the cystic duct and common bile duct in the pig makes it difficult for most to learn and practice laparoscopic common bile duct surgery. For this reason authors prepared a pig model by performing a common bile duct ligation 5–6 days prior to the planned training. The anatomy of the pig's biliary system is similar to the human, except for two things. The pancreatic duct does not enter the duodenum through the common bile duct ampulla, which means that the ligation of the distal common bile duct does not interfere with the pancreas. The other dissimilarity is that in pigs the cystic duct frequently arises from the right hepatic duct, which can make choledochoscopy more challenging. The ligation of CBD was also performed laparoscopically using clips. After as few as six days the CBD became dilated by 2 and 2·5 cm, and this was well tolerated by the animal. The training of advanced laparoscopic biliary procedures were thus possible as presented on the videotape, such as choledochoscopy, exploration of the bile duct, T-tube placement and it's fixation with intracorporeal suturing and knotting.

Supported by Hungarian grant OTKA T023338.

Transplantation

Technique for free intestinal loop for urethral reconstruction

J. Patricio, L. Silveira, J. Botelho and A. Bernardes *Department of Surgery I, Hospitais d a Universidade de Coimbra, 3049 Coimbra, Portugal*

The urethral reconstruction is a very complex problem and the usual techniques are often associated to a severe morbidity.

This video shows the appliance of a free intestinal graft for extensive urethroplasty. This method was studied in our Department and applied in man after several studies in the experimentation animal.

Two patients underwent perineal urethrostomy: one with partial loss of penis and urethral avulsion for trauma and the other with pseudo hermaphroditism.

All steps of this technique are visualized: receiver vessels building through saphenous vein grafts; intestinal loop gathering and transposition; 'neo urethra" diameter molding; follow-up.

After a period of 10 and four years respectively, the patients void well and uniformly. No complications have occurred.

Laparoscopic biliopancreatic bypass, experimental model

M.A. Bielsa, V. Aguilella, J.J. Resa, M.D. Arribas, I. Cruz, O. Burzaco, M. Elía and M. Martínez *Servico de Cirugía 'B', Hospital Clínico Universitario, Zaragoza, Spain*

Objective: In 150 vertical gastroplasties performed by our group for the treatment of morbid obesity with more than 10 years follow-up, the outcomes has not been as good as expected, with poor body mass loss and even refattening. Thus, we began to apply the biliopancreatic bypass which combines both restrictive and malabsorption techniques with a clinical experience of 30 patients in the last three years with good results and no complications. In this videotape we show an experimental variant of this technique outlined to be performed by laparoscopic approach in pigs, in order to further application in human surgery.
Method: The technique was carried out in 10 Landrace pigs. The follow up was seven days only because the aim of the study was to demonstrate the feasibility of the laparoscopic technique without complications.
Results: The biliopancreatic bypass was performed in all the animals with a mean operating time of 3·2 hours and without any intra or postoperative complication.
Technical description: After total anesthesia with orotracheal intubation, the animal is settled upwards and 20° antitrendelemburg. Once a pneumoperitoneum of 12 mmHg is created, five 12 mm ports are inserted. The liver is retracted right and upwards and the posterior space of the stomach is opened through the great omentum. An horizontal gastric stapling is performed, creating a proximal gastric pouch of 50 ml. Counting 250 cms. afterwards from the ileocecal valve, the jejunum is divided and an Y Roux loop is performed with first a gastrojejunal anastomosis and a jejunoileal anastomosis at 50 cms from the ileocecal junction. All this sutures were done by both endostapler and endostitches techniques.

An eventual iatrogenic choledocal lesion during a laparoscopic cholecystectomy. Main points to consider in order to avoid this complication

A. Gomez Portilla, B. Camps, C. Martinez de Lecea, J. Calvete, B. Ballester, J.V. Garcia Diez and F. Gomez Ferrer *Hospital Clinico Universitario, Valencia, Spain*

Aim of the study: This film is an attention call to all surgeons involved in laparoscopic surgery explaining the main points to keep in mind in order to prevent this unpleasant complication, how it happened and the way we treated it.
Material and methods: A real time iatrogenic choledocal lesion during a laparorscopic cholecystectomy is presented. We specially focus on the clue points that we retrospectively consider necessary to know in order to prevent this unlikely complication, the way how we resolved it and our current data with all the complications that we have suffered.
Conclusions: An iatrogenic lesion of the biliary tract during a laparoscopic cholecystectomy may happen in any laparoscopic procedure with independence of the surgeon experience. Knowledge of the main points to prevent this lesion is mandatory, as well as the way to repair the biliary tract.

Transcylindrical cholecystectomy. A new technique for minilaparotomy

E.J. Grau Talens, F. García Olives and M.P. Rupérez Arribas *Hospital Virgen del Toro, Department of Surgery, Calle Barcelona 3, 07701 Mahón, Menorca, Balearic Islands, Spain*

Introduction: Laparoscopic cholecystectomy has become the treatment of choice for cholelithiasis, but needs to be learnt and requires expensive materials. Minilaparotomy is not without difficulties. We present an original technique for minilaparotomy cholecystectomy, which facilitates the procedure.
Method: This technique is based on the introduction of a 10¥3·8 cm cylinder with a protruding plug on one end, through which we performed the cholecystectomy. A right epigastric incision of the same size as the cylinder (i.e. 4·5 cm) is made. One then proceeds to introduce the cylinder towards the Calot's triangle. Removal of the plug, neck traction and the help of little gauzes to reject neighbouring structures reveal a well defined and stable field, where it is easy to dissect the hepatocystic triangle, section duct and cystic artery between clips and, finally, remove it from the liver bed. Dissection is carried out with endoscopic or conventional materials.
Results: We have operated with this technique on 117 consecutive patients. A postoperative hospital stay of 1·8 days. Average operation is 43 minutes. Incision had to be enlarged on 12 instances; one wound infection. We have not had any main biliary duct injury. Postoperative VC and FEV1 have been reduced to a similar level to that of laparoscopic cholecystectomy.
Conclusion: Trancylindrical cholecystectomy is a fast and safe technique, and it is less expensive than laparoscopic cholecystectomy.

See better, find more, be not (so) invasive! The proper postprocessing methods in the evaluation of the HCTCA

K. Karlinger, E. Márton, E. Makó and T. Winternitz* *Department of Radiology and Oncotherapy and *1st Department of Surgery, Semmelweis Medical University, Budapest, Hungary*

Aim of the study: Among the investigation methods of bile ducts the HCTCA (Helical CT Cholangiography) is a relatively new, noninvasive imaging method.

Our experiences are based on more than 50 patients investigations by a spiral CT equipment.
Materials and methods: Hepatotrop contrast material has been adjusted intravenously in a long lasting infusion in order to reach reasonable opacification in the biliary system. The pictures have been taken in two delayed series (if necessary for the optimal filling, also in an additional one).

Because of the 3D reconstruction thin slices are recommended (2·5 mm).

After having the row data the pictures have been inspected by a normal mode each of the whole series has been evaluated by 3D rendering. Multiplanar reconstructions (MPR) have been made in all three dimensions and in any of the recommended supplementary planes. Maximum intensity projection (MIP) images have been reconstructed by subtracting the environment of the bile ducts. The spectacular and plastic shaded surface display (SSD) serves the better understanding for the surgeon.
Summary of results: In all cases, there was optimal opacification in the biliary tree. In 11 cases we found alterations intraductally, in 23 cases the reason of the disturbance was shown to be outside the biliary tract or the papill of Vater.
Conclusions: HCTCA is a very useful, noninvasive and tolerable tool for demonstrating the bile ducts and surrounding area. By using the proper method we can see little and even hypo-isodense stones intraductally, stricture or ligations on the biliary tract and anatomical variants. To apply the proper postprocessing method is important for getting relevant results.

The surgical technique of microlaparotomy cholecystectomy

I.I. Rozsos and J. Ferenczy *Moritz Kaposi Medical Center I. Department of Surgery, Kaposvár, Tallián, Gy. u. 20–34, Hungary 7400*

The conventional and laparoscopic cholecystectomy (LC) is as already every day utilized method, the operation procedure is well developed and the instruments used allow a reliable operation. The cholecystectomy performed by minilaparotomy is not yet a widespread procedure, the issue minilaparotomy has not been defined yet. The authors are demonstrating the surgical technique of microlaparotomy cholecystectomy (MLC) and the categorization of minilaparotomy. The gallbladder removal performed by abdominal incision less than 4 cm is via microlaparotomy, the 4–6 cm by modern mini- and the 6–8 cm via the conventional minilaparotomy cholecystectomy. For the success of operation a proper light source and the operative exposure are mandatory. In 2012 unselected cases operated for cholelithiasis and their complications, 92·5 per cent had MLC, 7 per cent required modern minilaparotomy, 0·3 per cent had classical mini and classical laparotomy. 17 per cent of the operations were termed as difficult. The majority of these were in the beginning as they found the best technique for the incisions and the exploration of the operative area, especially in obese patients. Inadequate lighting and exposure of the operating field were other factors. Also included are cases with difficult complicated pathology.

Acute emphisematous cholecystitis

J.M. Sousa, F. Miranda, A. Frias, M. Viana and C. Branco
Serviço de Cirurgia, Hospital Distrital de Aveiro, Av. Artur Ravara, 3800 Aveiro, Portugal

Acute emphysematous cholecystitis is a rare insidious and rapidly progressing disease that requires prompt surgical intervention.

The diagnosis is established usually when the plain abdominal X-ray shows gas within the gallbladder or in its wall.

It is important for the emergency physician to be aware of this clinical entity. The authors made a video showing the surgical approach, emphasizing the abdominal X-ray findings and ultrasound diagnosis.

Comments will be made during the video presentation and discussion after.

Turkish method: a safe, rapid method for laparoscopic cholecystectomy (610 cases)

K. Yüce* and L. Polat** **Dörtyol State Hospital, Department of General Surgery, Hatay, Turkiye; **Karacabey State Hospital, Department of General Surgery, Bursa, Turkiye*

Today, reports have been focused mainly on technical changes proposed to prevent the complications of laparoscopic surgical procedures. These techniques are gaseless procedures against the complications due to CO_2 and open laparoscopic procedures against the complications of Veress needle and the trocars. In order to overcome these complications, laparoscopic cholecystectomy technique by using three ports (Hatay triangle points) and low intraabdominal pressure (4–8 mmHg) in which Visiport$^{\text{TM}}$ (USSC) have been used as the first trocar – Turkish Methods –, was developed in Dörtyol State Hospital in 1993–94; which has the advantage of both gaseless technique and open laparoscopic technique and also time saving. 610 patients operated by using this technique have been reviewed in a prospective study.

Among the patients; 480 were female (av. age 47·3), 130 were male (av. age 52·4). 72 patients had acute (11·8 per cent), eight patients had sclerosing chronic cholecystitis. 15 patients had previous upper abdominal operations. The mean duration procedure was 26·3 min for female patients and 41·6 min for male. Drains were used in 60 patients (26 female,34 male). Fourth tricar was necessary for 12 patients (2 per cent). Eight patients necessitated conversion (1·3 per cent). Five patients had urgent relaparoscopy in the first postop. week; two patients had bleeding, three patients had biliary peritonitis. None of these patients necessitated laparotomy and were successfully managed by laparoscopic homeostasis, lavage and drainage techniques. Six patients had incisional hernia in the late postop. period. No mortality was encountered in these series.

As a result, we concluded that: a) the points of Hatay triangle were suitable sites of placing the trocars; b) Visiport$^{\text{TM}}$ (USSC) maintained a safe and rapid way of insufflation; and c) 4–8 mmHg CO_2 was enough for laparoscopic cholecystectomy.

Laparoscopic posterior truncal vagotomy and anterior linear gastrectomy

J. Vazquez Echarri, J.M. Romeo, C. Montes, A. Marinelli,
M.L. Ares, J. Martin Benito, M. Uribazo and J.L. Martinez Veiga
Serv. de Cirugía General y Digestiva, Hospital 'Severo Ochoa', Avd. de Orellana s/n, Leganes, 28911 Madrid, Spain

Introduction: Elective surgical treatment of duodenal ulcer has its indications. The laparoscopic approach offers clear advantages. We have carried out a laparoscopic approach using four truncal vagotomies with pyloroplasty, a posterior truncal vagotomy and seromyotomy and four posterior truncal vagotomies with anterior linear gastrectomy (PTV-ALG). In none of the cases of PTV-ALG existed symptoms of stenosis, the indication for surgery being poor response to medical treatment or episodes of upper gastrointestinal haemorrhage.
Material and methods: The patient is placed on the operating table in the supine position with 30° head-up tilt, with the surgeon between the legs of the patient. Five trocars are used, four of 10 mm placed in right midclavicular line, left anterior line, subxyphoid and upper middleline, where the optics of 0° is placed, and one of 12 mm in left midclavicular line. The dissection begins opening the pars condensa visualizing the right crura and opening the right phreno-esophageal space until location of the posterior vagal trunk. Section between clips of the vagal trunk. By means of three 3/0 silk stitches we mark 1- the starting point that includes the first branch of the crow foot, 2- the middle point near the lesser curvature and 3- the last once overcome the gastric fundus already in posterior face. The ALG is carried out by means of the successive application of endoGIA 30 helped with the tractors. We have needed between six and eight loads in order to complete the ALG.
Conclusions: Neither the time of evolution, or the number of cases are enough to allow any conclusions. Anyway, with more than a year of follow-up none of the cases have presented with ulcerous symptoms nor relapse.

A nylon guidewire for repeated oesophageal dilatations

Z. Górka, J. Nowak, H. Mekle, J. Słota, Z. Słabiak and P. Lampe
Department of Digestive Surgery, Silesian Academy of Medicine, 40-752 Katowice, 14 Medykȯw st., Poland

Conservative dilatation of oesophageal strictures (due to cancer, of corrosive ingestion, operative anastomoses) may be difficult, because of a tortous, kinked or very tight stricture canal or by atypical anatomical morphology. The introduced guidewire may get stuck, perforation is possible.

In the period 1975–1997 in 39 such patients with a difficult stenosis the authors applied a method with retrograde stricture dilatation and introduced nylon guidewire for long time repeated bougie dilatations.

Within a laparotomy and gastrotomy, up to the retrograde stricture dilatation, the wire was lead from the gastric lumen retrograde through the dilated stenosis to the throat and mouth or nose. The distal end of the wire through gastric and abdominal wall was fixed to the abdominal wall surface. The so introduced wire was later used as a guide for repeated dilatations. In nine patients the wire was used for over one year. Totally 135 dilatation procedures were performed. No complications related to the wire was observed. Transient clinical improvement was obtained in 22 patients and long lasting or permanent dilatation in 11. Technical details, clinical data of the patients, endoscopical and radiological documentation are presented by video.

A nylon guidewire installed for long duration can be used for repeated dilatations in difficult oesophageal stenoses.

Procedure of video assisted blunt dissection for patients with early esophageal cancer

M. Iwasa, A. Yamamoto, Y. Ohmori, Y. Iwasa, A. Inoue,
H. Maeda, M. Kume and S. Ogoshi *Department of Surgery II, Kochi Medical School, Nankoku, Kochi 783-8505 Japan*

Introduction: After stripping or blunt dissection of esophagus, it is common that the substitute of esophagus is passed through the retromediastinum to protect after bleeding and leak of air. We developed mediastinoscope with transparent optical sheath for observation to the retromediastinum space after stripping of the esophagus.
Material and methods: Eight patients with sm-pm esophageal cancer were applied this methods. Stages were diagnosed by endoscopic-ultrasound and/or CT. Optical sheath was made by poly vinyl chloride (PVC) and 33 cm of length and 2·3 cm diameter. It is consisted to double lumen of large lumen (15 mm diameter) for mediastinoscope and small lumen (5 mm diameter) for suction. Using the transparent optical sheath with mediastinal scope, surrounding connective tissues is dissected along to the esophagus from cervical incision and abdominal hiatus.

Adter that, the esophagus is pulled out from cervical region to abdomen by using vein stripper. The transparent optical sheath with mediastinal scope is inserted again from cervical region to retromediastinum for observation this procedure under video assisted.
Results and conclusion: After removing esophagus, the retromediastinum could be observed and bleeding and/or injuries of pleura were clearly detected and appropriate manoeuvre could be done with video monitor. Operative duration and blood loss were remarkably decreased in comparison with conventional thoracotomy method. There was no complications and this technique might be useful and safe for patients who receive the blunt dissection for early stage esophageal cancer.

Total laryngo-oesophaguectomy plus bilateral radical cervical lymphadenectomy for the treatment of a carcinoma of the cervical oesophagus

C. Serra, A. Baltasar, R. Bou, J. Del Río, M. Bengochea,
R. Martínez, F. Arlandis and C. Escrivá *Servicio de Cirugía General, Hospital 'Virgen de los Lirios', Polígono de Caramanxel s/n 03804 Alcoy, Alicante, Spain*

Introduction: Carcinomas of the cervical oesophagus usually have a bad prognosis and surgical treatment is difficult and extensive. Generally, curative procedures include en-block resections of neighbour organs.
Material and method: We present in this video the case of a 44-year-old male admitted with total dysphagia and 16 kg weight loss. The endoscopist found a stenotic tumour immediately above the vocal cords that needed dilatation to obtain a biopsy and showed an epidermoid carcinoma. CT scan defined the possible infiltration of the posterior wall of the trachea. Total parenteral nutrition was initiated a week before surgery.

En-block resection included a larynguectomy, thyroidectomy, total parathyroidectomy, bilateral radical cervical lymphadenectomy and transhiatal total oesophaguectomy. A gastroplasty via posterior mediastinum was chosen for the reconstruction making the anastomosis at the level of the pharynx and a very low tracheostomy was added.

The postoperative period was satisfactory. The patient needed oral support with thyroid hormone, calcium, vitamin D. Although calcium levels never raised above 6·5 mg/dl tetania episodes never occurred. Analysis of the specimen showed infiltration of the left thyroid capsulae and an only positive node belonging to the tracheo-oesophagic chain. Afterwards, adjuvant radiotherapy and chemotherapy was added.

Six months later patient weight was 48 kg and oral food intake was normal.
Conclusion: Carcinomas of the cervical oesophagus need aggressive surgical treatment even this may prove paliative. Short-term improvement of symptoms occurred in our patient, but further evaluation of results are to be made in the future.

Surgical treatment of achalasia by laparoscopy

J. Vazquez Echarri, J.M. Romeo, C. Montes, M.L. Ares, A. Marinelli, J. Martin Benito, M. Salvador, E. Gonzalez and J.L. Martinez Veiga *Serv. de Cirugía General y Digestiva, Hospital 'Severo Ochoa', Avd. de Orellana s/n, Leganes, 28911 Madrid, Spain*

Introduction: In spite of the fact that pneumatic dilation of the cardia in achalasia offers some acceptable results, dysphagia, although diminished, usually reappears during the first months. We show a Heller myotomy associated with a Dor fundoplication in an achalasia patient, sent directly to surgery without previous dilation. The patient complained for year and half of progressive dysphagia and regurgitation, having lost 6 kg of weight. The X-ray study, endoscopy and manometry were compatible with achalasia, with tendency towards vigorous type and LESP at rest of 36 mmHg.
Material and methods: Five trocars of 10 mm were used, placed in right midclavicular line, left anterior axillary line, left middle clavicular line, subxyphoyd and upper middle line where the optics of 0° was placed. We carried out the complete dissection of the esophagic hiatus. Once dissected both crura, the esophagus was isolated creating a posterior window from right to left, surrounding it with a ribbon. At least about 7 cm of esophagus was freed identifying and peserving the anterior vagus. The myotomy was carried out with scissors without electrocoagulation and maintaining an intraesophageal bougie of 40F, beginning 2 cm below the gastroesophageal junction. We used the cardial artery like anatomical reference. The myotomy was prolonged upwards in about 6 cm being testing by intraoperative endoscopy its completion and the absence of perforation. We performed a partial fundoplication Dor type to avoid the gastroesophageal reflux.
Conclusion: The postoperative evolution was satisfactory. After one year the patient is totally asymptomatic without dysphagia, nor pyrosis. The manometry show a high pressure zone of 3 cm of length with 8 mmHg and a pHmetry without pathologic reflux.

Stomach

Intraoperatory and videoscopic aspects of the pharyngocolical anastomoses within the oesophagoplastical surgery for postcaustical high oesophagian stenoses

S. Constantinoiu, D. Sarafoleanu, Fl. Chiru, A.R. Mocanu, R. Bârlă and M. Tocilescu *Surgery Clinic, 'St Maria' Clinical Hospital, Bd Ion Michalache (1 Mar), nr 37-39, sector 1, 78218 Bucharest, Romania*

The paper analyses the special aspects raised by four patients with postcaustical high oesophagian stenoses after their having taken caustical soda, with a high oesophagian total stenosis, two of them presenting also the burning of the epiglottis with a larynx stenosis (which needed traheostomy). After firstly having carried out a feeding gastrostomy with peritoneal collar – Gavriliu method, six months later we carried out an oesophagial by-pass with anizoperistalatic left colon, two with presternal colon and two retrosternally. The cervical anastomosis was carried out in the second stage, and, due to the oesophagian total stenosis, it consised of latero-lateral pharyngo-colonoanastomosis, with extramucous monolayer threads on the colon and total ones on the pharynx; in two cases the pharyngotomy has been carried out in the hyoid bone bed after its partial resection, and other two cases the pharyngotomy was carried out through a transverse incision, subhyoidal.

After a radiological and videoendoscopic control which noticed the cervical pharyngocolic anastomosis integrity, the feeding per os was resumed in two weeks, the gastrostomy was eliminated after other two weeks.

The postoperatory functional result was very good in all the four cases, the patients putting on weight, 5 to 25 kg within the first postoperatory year.

Laparoscopic surgery of the retroperitoneal organs

S. Duca, I. Coman, C. Iancu, O. Bala, D. Munteanu and H. Radu
Surgical Clinic no. III, Str. Croitorilor 19-21, 3400, Cluj, Romania

A laparoscopic transperitoneal approach was used for the kidney and adrenal glands In the case of serous renal cysts, unroofing of the prominent dome was performed Seventeen patients were operated, 14 with right renal cysts and three with left ones. The diameter of the cysts ranged between 6 and 14 cm. Average operative time was 50 minutes. There were no incidents, nor postoperative complications.

Laparoscopic nephrectomy was performed in five cases, all for sclero-atrophic kidneys of inflammatory origin. There were three right and two left nephrectomies On the left side operation is more difficult due to close relation to the left colon and spleen. From the very beginning it is necessary to find and section the urether, because its proximal stump will serve for suspending the organ and as a guide to progress with the dissection towards the renal hilum. On the right side, for a better operative exposure, one must also perform a Kocher manoeuvre

One laparoscopic nephropexy, using a polyglactinic mesh after Hubners technique, was performed, for a right renal third degree ptosis.

Right adrenalectomy was performed in two cases for benign tumours, 4–5 cm in diameter and in one case for an adrenal cyst. Left adrenalectomy was performed in one case For a proper exposure of the adrenal gland and its middle venous pedicle on the right it is recommended to perform a partial duodeno-pancreatic mobilization. On the left, mobilization of the left colon and spleen are essential. Following these steps, blood loss was minimal and adrenalectomy much eased.

The most demanding operations were the nephrectomy and the nephropexy, needing between 3–5 hours to be completed. There were no postoperative complications, all patients being discharged cured.

Laparoscopic treatment of parahiatal hernias

M. Felices Montes, R. Toscano Méndez and C. Vara Thorbeck
Carlos Vara Thorbeck, Paseo Miramar No. 31, 29016, Malaga, Spain

Surgery avoids the potential complications of large hiatus hernias The long incision of the classical abdominal and thoracic approaches are associated with pulmonary infections and slow recoveries. Laparoscopic surgery avoids these problems and offers a number of advantages. Our video shows three cases of the total of 10 patients that we have operated with laparoscopic technique.

Methods: We reduced the paraesophageal hernias and partially or completely resected the sack of three patients as we show in the video. Large diaphragmatic defects were repaired with non-absorbable sutures, no mesh was used The procedure ended with either a Nissen's or Dor fundiplication antireflux technique.

Results: Mean operating time was 90 minutes. Patients had oral tolerance to diet at 24 hours and left hospital on the fourth postoperative day. There was no case of relapse at six months follow-up.

Conclusions: Laparoscopic treatment of large paraesophageal hernias offers an excellent therapeutic alternative to open surgery; less infection, faster recoveries and shorter hospital stays. Fields of view of anatomical structures are better than open surgery.

Laparoscopic inguinal hernia repair using a totally extraperitoneal approach

X. Feliu, R. Clavería, E. Fernández-Sallent, E. Macarulla, P. Besora, J. Camps and J. Basas *Department of Surgery, Hospital General d'Igualada, P. Verdaguer 128, 08700 Igualada, Barcelona, Spain*

Totally extraperitoneal herniorraphy (TEP) probably is the best laparoscopic inguinal hernia repair technique because it is based on classic open preperitoneal procedure with the advantages of the laparoscopic approach

The peritoneum is kept intact, avoiding the potential risk of damaging intra-abdominal organs, pneumoperitoneum or vascular injury. Spinal anesthesia can be used.

Definitely, the TEP is a laparoscopic modification of Stoppa's open operation concerning a dissection and mesh placement, improving the approach and thus, giving better postoperative comfort.

We present the technical steps and the most important anatomical references 1) Dissection balloon is used to facilitate preperitoneal space dissection. 2) Two 5 mm trocars in abdominal middle line are placed. 3) Anatomical dissection landmarks. Cooper ligament, epigastrics vessels to know the type of hernia; iliopubic tract, inguinal internal ring, psoas. 4) Dissection of the elements of the cord avoiding missed indirect hernial sac, the most important cause of recurrence during the learning curve (retained recurrences). 5) The mesh is introduced through the 10 mm umbilical trocar and positioned over the entire musculopectineal orifices with sufficient overlap at the medial and lateral borders. The size is 14 × 11 cm without cuts. 6) The helicoidal stapler is used to fixate the mesh.

Flexible choledochoscopy: technical improvements and indications

*J.M. Fernández, J. Muñoz, F Blasco, R. Partida and J. Tirapo
General and Digestive Surgery Service, Hospital 'Cruz Roja' INSALUD, Ceuta, Spain

The choledocoschopy (CD) represents the only exploration that allows a direct view of the intra and extrahepatic biliary tract, with a 75–85 per cent sensitivity and 100 per cent specificity in diagnosis of neoplasms and lithiasis. It reduces the retained stone rate from 9–14 per cent to 1–3 per cent. We adopted the CD with a flexible instrument, 4-6 mm in diameter, as the routine exploration of the biliary system when the preoperative studies or intraoperative evaluation suggest biliary pathology. It could or could be not preceded by intraoperative cholangiography. We can also make biopsies and remove stones through the work channel The CD can be done through a choledochotomy or the cyshie duct given a previous balloon dilatation. The procedure lasts an average of 20 minutes and needs the continuous perfusion of normal saline solution at a pressure no higher than 100 mmHg. The CD is connected to the laparoscopic camera and the images are seen on the video screen We present six patients with different diseases who demonstrate the usefulness of the procedure There was no morbidity related to the procedure We saw a significant improvement in the number of primary closure of the bile duct since we started the CD. We were not able to complete the CD with the laparoscopic approach. The most important technical problem that occurred was when we tried to visualize the hepatic confluence, because of the extension of the common wall between the cystic duct and the common hepatic

Pediatric endoscopic surgery

*Ch. Grapin, *F. Fayad and **N. Sellier **Department of Pediatric Surgery, Hopital Jean Verdier 93140 Bondy, France*

The minimally invasive procedures are now being successfully applied to pediatric surgical procedures such as cholecystectomy, cryptorchidism, diagnostics of inner genitalia, peritonitis, thoracosopy.

The anticipated benefits of these techniques include less postoperative pain, shorter hospital stay, and lower hospital costs, with a quicker return to normal activity. Obviously, a number of precautions should be taken in children: the use of open laparoscopy seems the main point.

This video (30 mn) shows the main indications of laparoscopy in childhood: appendectomy, gastroesophageal reflux, abdominal cryptorchidism, ovarian cysts, splenectomy, nephrectomy and thoracoscopy.

Laparoscopic operation of double-splitting hiatal hernia

*Z. Hajdu, *M. Molnár, *L. Bokor, *Z. Szegedi, *S. Kathy and †R. Bagi **Department of Surgery, Kenézy Teaching Hospital of Medical University School, Debrecen, †Ethicon Endo-Surgery, Hungary*

Introduction: The method of laparoscopic repair of hiatal hernia is accepted in surgery.

Methods: Between January 1994 and December 1998 authors have done 125 laparoscopic operations. They would like to demonstrate the most difficult hiatal reconstruction, where they have treated a large hiatal hernia. The three-fourth of the stomach was in the thoracic cavity partly through the hiatus and partly through the right ruptured crus itself. The authors demonstrate their procedure and the use of Harmonic Scalpel.

Results: During their operation they did not have any secondary injury. There was no need for tranfusion. Their patient was completely pleased with the results after discharge, still is under regular control. In the demonstrated rolling-hernia operation the advantages of Harmonic Scalpel were: clean, bloodless operating field; easy and safe transsection of vessels and tissue; shorter operation time.

Conclusion: Based on their experiences and on the data of literature the laparoscopic technique is a feasible method in the treatment of hiatal hernia.

Laparoscopic reoperation after laparoscopic hiatal reconstruction

Z. Hajdu, S. Kathy, L. Bokor and Z. Szegedi *Department of Surgery, Kenézy Teaching Hospital of Medical University School, Debrecen, Bartók B. 2-26, 4043, Hungary*

Introduction: The laparoscopic hiatal reconstruction is accepted treatment of hiatal hernia. In cases of recurrent hernias the accepted treatment mostly is the open reoperation that means the reconstruction of the incorrect hiatus and fundoplication.

Methods: A 68-year-old woman was operated for paraesophageal hiatal hernia. Laparoscopic hiatal reconstruction with Nissen fundoplication was performed. She developed a recurrent paraesophageal hernia. We performed a re-laparoscopy and we realised tearing of the crural stitches, opening of the hiatus and hernialisation of the fundus of stomach. A laparoscopic hiatal reconstruction and Toupet fundoplication was performed.

Results: The hernia was withdrawn, the hiatus was correctly closed, the fundus was fixed and the fundoplication was performed entirely laparoscopically. There was no intraoperative complications. Operation time was 65 minutes. The postoperative course was uneventful, and radiologic examination showed lack of hiatal hernia. Six months later our patient has no complaints.

Conclusion: The treatment of failed laparoscopic hiatal reconstruction generally requires reoperation. Open procedure is recommended to make a correct solution. In special cases during laparoscopic reoperation (re-laparoscopy) reconstruction of hiatus could be performed with success.

Laparoscopic treatment of perforated peptic ulcer: first experience

N. Kaselis, A. Montvydas, A. Slepavicius and N. Noreika *Klaipeda Hospital, Liepojos 15, Klaipeda, 5800 Lithuania*

It is accepted that emergency treatment of perforated peptic ulcer is based on the surgery, namely simple closure or more definitive ulcer surgery. The preliminary results of laparoscopic treatment of 11 patients with peptic ulcer perforation are reported here.

For patients with perforated peptic ulcer, without ulcer history, we perform laparoscopic duodenorrhaphy with omental patch repair. We used this method in 11 patients. Ten of them were males (age from 20 to 41 years). Mean time from perforation until operation was 7 hours 42 minutes (range 3–15 hours). The perforation of duodenum ulcer with serofibrinous peritonitis was found during laparoscopy in all cases. Ulcers were sutured by vicryl sutures. Additional sutures with omental patch were passed to surround the perforation. This was followed by peritoneal lavage with normal saline. At the end of operation the tubes under the liver and in pelvis minoris were left. The operation lasted for a mean time 75 minutes (range 40–135 minutes). For the protection of duodenal suture, in the case of big perforation hole (0·8 cm), nasograstric tube was left for two days in two of the operated patients.

Next day postoperatively all patients started to walk, only non-narcotic analgetics were applied. No leakage was demonstrated and no postoperative complications accrued. No conversions were needed in our practice. The mean hospital stay was 7·9 (range 7–14) days.

One month later, during control fibrogastroduodenoscopy, healed ulcer scars were found, no gastric evacuation disorders were demonstrated.

Conclusion: The laparoscopic surgery of perforated peptic ulcers is effective in the first hours after perforation.

Operating technique and early results of endoscopic subfascial division of perforating veins

D.Z. Kuś, W. Jóźwiak, D. Kaczmarczyk, P. Zydlewski and W. Stryga *St. Anna District Hospital of Traumatic Surgery, Department of General Surgery, ul. Barska 16/20; 02-315 Warsaw, Poland*

Introduction: Direct surgical ligation of incompetent perforating veins has been reported to effectively treat severe chronic venous insufficiency. Although it could be associated with significant wound complications. We present our operating technique and early results of endoscopic subfascial division of the perforating veins.

Materials and methods: From July 25, 1996 to December 31, 1997, 27 legs in 21 patients (12 female, 9 male) were treated with endoscopic subfascial division of perforating veins. Seventeen of the 27 legs had active or recently healed venous ulcers. Mean duration of the ulcerations was 7·3 years. Standard laparoscopic equipment with two 10-mm ports was used to perform clipping and division of medial perforating veins through two small incisions made just below the knee, avoiding the area of ulcer. Carbon dioxide was insufflated at a pressure of 30 mmHg into the subfascial space to facilitate dissection, and a pneumatic thigh tourniquet (300 mmHg) was used to obtain bloodless operating field. Additional removal of superficial veins was performed in 17 limbs.

Results: A mean of 4·1 perforating veins (range 1–6) were divided; tourniquet time averaged 45 minutes (range 30–110). We observed no wound infection. Superficial thrombophlebitis was an early complication and occurred in one patient. In 22 legs the ulcer healed and symptoms resolved. In three legs the ulceration improved and in two it was unchanged.

Conclusions: Endoscopic subfascial division is a safe and precise technique avoiding skin incisions in the ulcer area. This method allows us to reach all of the medial perforators. It could be used successfully in management for patients with most severe forms of active or healed venous ulcers.

Gasless laparoscopic cholecystectomy with mini-instruments (2 mm) video

M.J. Queiroz-Medeiros, A. Menezes-Silva, J.R. Raposo d'Almeida, H. Vasconcelos Dias, J.L. Nunes and C. Balhana
Department of Surgery, Hospital de Pulido Valente, New University of Lisbon, Alameda das Linhas de Torres, 117-1750 Lisbon, Portugal

Gasless laparoscopy, in which abdominal distension is provided by an abdominal wall lifting device, has been our choice for patients undergoing laparoscopic surgery. Cholecystectomy has been performed in 450 successive patients with good results. Recently, we started practising this type of operation using instruments with 2 mm of diameter. The video demonstrates, step by step, the possibility of performing a cholecystectomy with three ports of 2 mm and a fourth one periumbilical of 10 mm parts Using gasless technique (we will show the abdominal wall lifting device – Laparolift®, Origin Medsystems – which is necessary to produce the working chamber) we achieved a very good vision and an excellent exposure of the cystic duct, the artery and the common bile duct. As usual with this technique, irrigation and suction were very helpful and the 2 mm suction device made the dissection of the triangle of Calor very easy to perform. The laparoscope and the endoclip applier were introduced through the periumbilical port, which was also utilized to remove the gallbladder.

For cholecystectomy we usually insert only three trocars (one 5 mm and two 10 mm). However, we consider advisable to insert a fourth port, when using smaller instruments, to make surgery more comfortable and safer

Laparoscopic truncal vagotomy and antrectomy (video)

J Raposo d'Almeida, A. Menezes Silva, H. Vasconcelos Dias and M.J. Queiroz-Medeiros *Department of Surgery, Hospital de Pulido Valente, New University of Lisbon, Alameda das Linhas de Torres, 117-1750 Lisbon, Portugal*

We present a video demonstrating that Laparoscopic Truncal Vagotomy and Antrectomy can be safely carried out without CO_2 pneumoperitoneum. We performed this operation in a patient with four recurrences of gastric ulcer after medical treatment and maintenacne therapy Preoperative work-up included upper endoscopy with target biopsy of the edge.

In order to perform the operation we used, as usual, an abdominal wall lifting device (Laparolift®, Origin Medystems) which is necessary to produce the working chamber The operation was carried out according to the classic steps of truncal vagotomy and antrectomy (Billroth II, antecolic), but under gasless laparoscopic surgery. Unstressed access to the patient and clear visualisation of the anatomy is possible with gasless technique which is compatible with the use of conventional instruments which make surgery easier. The technique greatly reduces potential patient morbidity associated with CO_2 pneumoperitoneum, particularly pneumothoraces and emphysema Anaesthetists report little difficulty performing their duties.

The use of ultrasonic energy in the laparoscopic cholecystectomy

G. Savanis, G. Velimezis, V. Patrikakos, I. Antoniadis and E. Perrakis *Department of Surgery, Western Attika General Hospital Dodekanisou 1, Athens, Greece*

Aim: The aim of this study is to demonstrate our experience on the use of the ultrasonically activated scalpel (UAS) in the laparoscopic cholecystectomy (L.C.).

Methods: Between January and December 1997 the UAS was applied in 240 patients who underwent L.C. (164 females, 76 males, mean age 56·5 years) Local findings during the operation were: 180 uncomplicated cholelithiasis, 22 acute cholecystitis, 17 gallbladder empyema, 13 hydrops, eight lithiasis with liver cirrhosis of Child-stage A and B (3·3 per cent)

Results: There was one conversion to open procedure, but not due to the UAS. The mean operative time after the first 10 procedures was 15 min (5–33 min), in average 4 min shorter than with electrosurgery The incidence of gallbladder perforation from the device itself was one per cent The mean length of postoperative hospital stay was 2·5±0·5 days. There was significantly less fluid amount from the drain in comparison with patients operated with electrosurgery The complete technique is demonstrated in the video tape.

Conclusions: The experienced advantages of the UAS in the L.C. over electrocautery can be summarized as following:

1. Safe and effective hemostasis, especially needed in cirrhotic patients
2. Minimal tissue injury and low incidence of Gallbladder perforation during dissection with the device.
3. No risk of inadvertent distant injury resulting from arcing and sparking
4. No smoke generation and clear visual field.
5. Reduced operative time
6. No need for patient grounding
7. No use of dissector and scissor. The procedure can be carried out with the use of the UAS alone and this reduces significantly the cost
8. Drainage can be avoided in most of the cases.

The laparoscopic extirpation of a wandering spleen

P. Van De Walle, B. Dillemans, M. Vandelanotte and L. Proot
Department of General, Vascular and Paediatric Surgery, AZ St-Jan Bruges, Bruges, Belgium

A 79-year-old female patient with chronic lymphatic leukemia since 1971 was presented with a severe relapse of autoimmune thrombocytopenia. The patient already underwent an irradiation of the spleen with a maximum dose of 24 Gray Now the thrombocytopenia was resistent to medical therapy with leukeran, corticosteroids and immunoglobulins. As further irradiation was not possible, splenectomy was considered On preoperative computed tomography scan of the abdomen the spleen was localized in the left fossa and hypogastrinum. The total length of the spleen was 14·7 cm. The ectopic spleen with a weight of 885 gramme was successfully removed by the laparoscopic approach. Histopathology revealed invasion of the spleen by CLL. After the splenectomy normalization of the thrombocytes occurred (250 000 on the day of discharge).

The laparoscopic marsupialization of a giant post-traumatic cyst of the spleen

P. Van De Walle, B. Dillemans, M. Vandelanotte and L. Proot
Department of General, Vascular and Paediatric Surgery, AZ St-Jan Bruges, Bruges, Belgium

A 26-year-old female patient was transferred from the gastro-enterology department with a history of increasing pain in the left upper quadrant of the abdomen. Sometimes there was irradiation of the pain to the left thoracic region or to the left fossa Furthermore, there were complaints of weariness and shortness of breath in doing daily activities. On abdominal examination a spherical mass was felt in the left upper quadrant. Echography of the abdomen showed a thin walled cyst with homogeneous content and a diameter of 140 mm Computed tomography scan of the abdomen showed a giant splenic cyst with a cross sectional diameter of 17 cm and a height of 16 cm A laparoscopic approach was proposed with further decision making based on the frozen sections during the operation. A successful laparoscopic marsupialization was performed.

Laparoscopic Nissen-Rossetti fundoplication

J. Vazquez Echarri, J.M Romeo, C. Montes, M.L. Ares, M. Uribazo, J. Martin Benito, J. Escudero, R. Llorente and J.L. Martinez Veiga *Serv. de Cirugía General y Digestiva, Hospital 'Severo Ochoa', Avd. de Orellana s/n, Leganes, 28911 Madrid, Spain*

The surgical treatment of the gastroesophageal reflux represents a clear indication for a laparoscopic approach. The laparoscopy allows the same surgical technique diminishing the surgical trauma.

From November 1992 to December 1997 we have performed this technique in 92 patients. The surgical technique was similar in all the cases although with the learning curve the operative time declined from 4 to 1·5 hours, the mean of the series 134 minutes. Five trocars of 10 mm are used, right hypohondrium, left anterior axillary line, left middleclavicular line, subxyphoyd and upper middle line for the optics of 0°. We begin the dissection opening the pars condensa, visualising the right crura and opening the phreno-esophageal space. Once dissected both crura, we carry out the isolation of the esophagus creating a posterior window by dissecting right to left. Later on, we complete the dissection of both cruras, and liberate the His angle and the gastric fundus without section of the short gastric vessels. In all the cases we carried out a crura repair, with one to four stitches. In 89 cases we carried out a short Nissen-Rossetti fundoplication of about 2·5–3 cm, with three sutures, using the anterior face of the gastric fundus to perform a valve without section of short gastric vessels. In 64 cases we used a 50F intraesophageal bougie for calibration. In two cases we carried out an anterior fundoplication Dor type, in one for technical reasons and in the other for manometric contraindication to complete fundoplication. In the last 32 cases the valve was sutured to the right crura to avoid a torsion effect. In a case conversion to open fundoplication for haemorrhage was necessary. Cholecystectomy was associated in 14 cases.

Operative strategy in laparoscopic splenectomy

J. Vazquez Echarri, J.M. Romeo, R. Llorente, C. Montes, A. Marinelli, M.L. Ares, A. Garcia Alvarez, J. Martin Benito, D. Lacasa and J.L. Martinez Veiga *Serv. de Cirugía General y Digestiva, Hospital 'Severo Ochoa', Avd. de Orellana s/n, Leganes, 28911 Madrid, Spain*

Introduction: The laparoscopic splenectomy is suitable in spleens of less than 20 cm in length, and especially when it is possible their fragmentation for extraction as ITP and spherocytosis.

Material and methods: The placement of the patient is in supine decubitus with 30° head-up tilt and about 45° right lateral tilt. The surgeon stands between the legs of the patient. Four trocars, three of 10 mm and one of 12 mm, are positioned in middle line under xyphoyd, between umbilicus and xyphoyd, anterior axillary line subcostal (0° telescope) and middle axillary line subcostal (12 mm). In the last four cases the patient was placed in the lateral decubitus position. The dissection begins in the inferior pole of the spleen, liberating the splenic angle of the colon and, isolating and dividing between clips the vascularization of the inferior pole. The inferior pole is rised, sectioning the renalsplenic ligament and the fatty tissue of the inferior border of the hilius. We continue cephalad by opening the anterior face of the gastrosplenic ligament and dividing between clips the short gastric vessels. Later on, maintaining the spleen rised, we continue with the liberation of the renalsplenic ligament up to identify the hilar vessels isolated from the pancreatic tail, proceeding to their section with endoGIA. The liberation is finished with the section of the splenophrenic ligament. Later on, the spleen is introduced into a plastic bag. The bag is closed by tightening the pursestring at its top and is partially pulled out of the abdomen through the 12 mm trocar. The spleen is morcellated within the bag and removed.

Conclusions: During the last three years we have operated on with this technique 18 patients. In a case, the first of the series, it was necessary the conversion to laparotomy for haemorrhage and another case was reoperated in the postoperative period. In a case we associated a cholecystectomy.

Laparoscopic posterior truncal vagotomy and anterior linear gastrectomy

J. Vazquez Echarri, J.M. Romeo, C. Montes, A. Marinelli, M.L. Ares, J. Martin Benito, M. Uribazo and J.L. Martinez Veiga
Serv. de Cirugía General y Digestiva, Hospital 'Severo Ochoa', Avd. de Orellana s/n, Leganes, 28911 Madrid, Spain

Introduction: Elective surgical treatment of duodenal ulcer has its indications. The laparoscopic approach offers clear advantages. We have carried out a laparoscopic approach using four truncal vagotomies with pyloroplasty, a posterior truncal vagotomy and seromyotomy and four posterior truncal vagotomies with anterior linear gastrectomy (PTV-ALG). In none of the cases of PTV-ALG existed symptoms of stenosis, the indication for surgery being poor response to medical treatment or episodes of upper gastrointestinal haemorrhage.

Material and methods: The patient is placed on the operating table in the supine position with 30° head-up tilt, with the surgeon between the legs of the patient. Five trocars are used, four of 10 mm placed in right midclavicular line, left anterior line, subxyphoid and upper middleline, where the optics of 0° is placed, and one of 12 mm in left midclavicular line. The dissection begins opening the pars condensa visualizing the right crura and opening the right phreno-esophageal space until location of the posterior vagal trunk. Section between clips of the vagal trunk. By means of three 3/0 silk stitches we mark 1- the starting point that includes the first branch of the crow foot, 2- the middle point near the lesser curvature and 3- the last once overcome the gastric fundus already in posterior face. The ALG is carried out by means of the successive application of endoGIA 30 helped with the tractors. We have needed between six and eight loads in order to complete the ALG.

Conclusions: Neither the time of evolution, or the number of cases are enough to allow any conclusions. Anyway, with more than a year of follow-up none of the cases have presented with ulcerous symptoms nor relapse.

Laparoscopic pericystectomy with the harmonic scalpel for hepatic hydatidosis: case report

A. Alper, I. Özden, O. Bilge, Y. Tekant, L. Avtan, K. Acarli, A. Emre and O. Ariogul *Istanbul Faculty of Medicine, Hepato-pancreato-biliary Surgery Unit, 34390 Capa, Turkey*

In this videoband, we present a case of hepatic hydatidosis treated by pericystectomy with the aid of the 'harmonic scalpel' apparatus (Ethicon).

The patient was a 47-year-old man with a computerized tomography revealed Gharbi grade III exophytic lesion (8 × 6 cm) at segment III. At the laparoscopic exploration, the cyst was found to be covered with omental adhesions which were divided with the aid of 'harmonic shears'. The cyst was removed by cutting in the plane between the cyst and hepatic paranchyma in the coagulation mode of the apparatus at full energy. Two hepatic ven branches (1–1·5 mm) and an arterial branch (1 mm) were observed as disting structures and secured with clips. At the end of the procedure, there was only minimal bleeding from the liver surface and this was controlled with the argon beam coagulator. Then the cyst was placed into a plastic bag and extracted after the cyst contents were partially removed. The postoperative course of the patient was uneventful. He was discharged after two days.

The harmonic scalpel greatly facilitates the procedure by sealing the 'raw' liver surface effectively, i.e. there was no leakage of bile and only minimal bleeding. With the aid of 'harmonic scalpel' or a similar apparatus, pericystectomy can be conveniently added to the armementarium of the laparoscopic surgeon. This operation should be performed in the institutions with extensive experience in both laparoscopic and hepatobiliary surgery.

Oesophageal epidermoid carcinoma: results of surgery after neoadjuvant radiochemotherapy

*M. Adham, *J. Baulleux, †J.P. Gerard, E. Delaroche, *N. Berthoux and *C. Ducerf *Department of General, Gastrointestinal Surgery and Liver Transplantation, Croix Rousse Hospital, Lyon, France. †Department of Radiotherapy, Centre Hospitalier Lyon Sud Lyon, France*

While surgery still remains the treatment of choice for oesophageal epidermoid carcinoma, there was no improvement of the survival rate in the past decades with 18 per cent five years actuarial survival. The aim of this study was to evaluate the interest of surgery after neoadjuvant radiochemotherapy to 1) increase the resection rate, 2) improve the actuarial survival rate, 3) increase the disease free survival (DFS), 4) avoid mutilating surgery. From February 1987 to September 1997, 55 patients (49 men and six women) with a mean age of 58±8 years (from 77 to 38) received oesophageal resection after neoadjuvant treatment. In eight cases there was a previous history of ENT epidermoid carcinoma. Tumour location was: upper 1/3 $n=19$, middle 1/3 $n=22$, lower 1/3 $n=9$ and double localisation in upper and lower 1/3 $n=5$. Impassable stenosis was observed in 20 cases. Thirty-five patients had endosonography, and tumour classification was mainly uT3 $n=25$ (45·5 per cent), uT4 $n=6$ (11 per cent) and uN1 $n=25$ (45·5 per cent), uN2 $n=6$ (11 per cent), the other patients were: uT0 $n=1$, uT1 $n=1$, uT2 $n=4$, uTx $n=3$, uN0 $n=5$, uNx $n=4$. Neoadjuvant treatment included two courses of chemotherapy 5-Fluorouracil (1 g/m^2/day) and Cisplatin (25 mg/m^2/day) from day 1 to day 5, and from day 21 to day 26 where half dose of 5FU was given. Radiotherapy was done from day 21 to day 36 giving a total of 36 grays. Full neoadjuvant treatment was possible in 67·3 per cent of cases, radiotherapy was completed in 85·5 per cent, and uneventful course was achieved in 56·4 per cent. Surgery was performed one month after the end of radiotherapy (at day 60). Tumour resectability was 96·4 per cent, only two patients had surgical exploration without tumour resection. Complete (curative) resection was achieved in 45 cases (82 per cent), and in eight cases (14·5 per cent) palliative resection was done. Forty-seven patients had gastroplasty and two had coloplasty. Three field lymphadenectomy was done in 38 cases (69 per cent) and two field lymphadenectomy in 15 cases (27 per cent). Operative mortality was nil, and hospital mortality was 7·3 per cent. The postoperative course was uneventful in 45·5 per cent of patients, complications that occurred were mainly pulmonary (34·5 per cent) and recurrent nerve palsy (23·6 per cent). Pathological tumour classification (AJCC 1988) was: Stage 2a $n=6$, Stage 2b $n=3$, Stage 3 $n=8$ (14·5 per cent), Stage 4 $n=13$ (24 per cent), and in 23 cases (42 per cent) the tumour was totally (or almost) sterilised (R±). Larynx preservation was achieved in 10 of 12 patients with theoretical indication of total pharyngolaryngoesophagectomy. The overall actuarial survival rate was 27 per cent and 22 per cent at four and nine years. The DFS was 28 per cent and 25 per cent respectively. Sixteen patients died with local or metastatic recurrence, and 19 are living (17 are disease free and two with metastasis). In the group R±, the actuarial survival rate was 53 per cent and 46 per cent at four and nine years, and the DFS was 46 per cent and 47 per cent respectively. Six patients died without recurrence and 12 are living and disease free. Neoadjuvant treatment is well tolerated by almost all patients when carefully selected. It appears that this combination therapy increases tumour resectability, it can allow in some cases laryngeal preservation. Significant improvement of the actuarial survival rate and DFS is observed in the R± group.

Antroduodenal motility in patients with gastroesophageal reflux disease and gastric symptoms

J. Heimbucher, K.-H. Fuchs, M.P. Ritter, S.M. Freys and A. Thiede *Chirurgische Universitätsklinik, J. Schneiderstr. 2, 97080 Würzburg, Germany*

Background: A considerable percentage of patients with gastroesophageal reflux disease present with gastric symptoms in addition to typical reflux symptoms. The underlying motility of the stomach and/or duodenum is poorly understood.

Aim: To characterize antroduodenal motility in patients with GERD and gastric symptoms.

Material and methods: Thirty-four patients (25 male, 9 female, age 25–78 years) with increased esophageal acid exposure on 24 hour esophageal pH monitoring (DeMeester score >14·7) and 38 healthy volunteers underwent 24 hour ambulatory antroduodenal manometry studies. The majority of patients (85 per cent) presented with gastric symptoms (nausea and vomiting, fullness, early satiety) in addition to typical reflux symptoms, the others had an increased Bilirubin exposure of the stomach and/or delayed gastric emptying. The total number and the duration of complete interdigestive motor cycles (IMC's) was analysed. The contraction frequency in the antrum and duodenum was calculated for the total, upright, supine and postprandial study period. Results were compared with the data of the 38 healthy volunteers.

Results: GERD-patients showed a lower total number of interdigestive motor cycles (IMC's) in the antrum and duodenum when compared to healthy volunteers (table). The postprandial contraction frequency in the antrum and duodenum was lower than in normal controls (table).

		Antrum			Duodenum		
		Control	GERD	*P*	Control	GERD	*P*
IMC	number/24 h	5	3	<0·05	8	4	<0·01
	duration (min)	120	122	n.s.	65	76	<0·05
Frequency	total	1·13	0·83	<0·01	1·82	1·93	n.s.
	upright	1·38	1·33	n.s.	2·12	1·86	n.s.
	supine	0·65	0·33	<0·01	1·11	1	n.s.
	postprandial	1·74	0·96	<0·05	4·68	3·22	<0·01

Values indicate median.

Conclusion: Patients with gastroesophageal reflux disease and gastric symptoms have reduced foregut motility which could compromise the outcome after antireflux surgery.

Scintigraphic findings correlate with symptomatology in esophagoplasty function evaluation

*N. Kavallieratos, †P. Yannopoulos and ‡A. Stavraka-Kakkavaki
**1st General Department, Gen. Reg. Hospital Nikea, Piraeus*
†2nd Surgery Department, 'Evangelismos' Hospital, Athens
‡Nuclear Medicine Section, Roentgenol Laboratory of Athens University, Greece

Background: Esophagoplasty is nowadays a well-established surgical procedure for palliation or cure of malignant as well as benign esophageal disease. Apart from the underlying disease, quality of life depends on long-term functional results. Scintigraphy is a relatively simple well tolerated method of esophagoplasty function evaluation.
Material and methods: Thirty-one patients having undergone esophageal resection and substitution (n=24, 77·4 per cent) or bypass (n=7, 22·6 per cent) have been studied 3–186 months after the operation. Data concerning kind of operation, nutritional state, ability to swallow and symptoms as vomit, a feeling of 'fullness' or 'spasm' have been recorded. The patient was examined fasting for at least six hours. 1 mCi of 99 mTc sulfur colloid in 10 ml of tap water were given orally and the patient was instructed to swallow it at once and not swallow his saliva for 32 seconds. Examination was performed in supine position before and after taking sitting position, so that the role of gravity could be estimated.
Results: Transit time of 30 per cent of radioactivity exceeded 1312 seconds in 83·9 per cent of cases. 32 seconds clearance ranged from 3·12 per cent to 58·69 per cent. Even the best results of substitute transit and clearance were statistically highly significantly worse than the ones of a group of healthy volunteers. Best functional results have been observed in patients with jejunum or iso- or antiperistaltic gastric tubes. Substitute clearance due to gravity was the main contributor to overall clearance, especially in cases of whole stomach, and correlated well with present nutritional state (percentage of ideal weight). Scintigraphy was specific but not sensitive in revealing reflux to the substitute causing symptomatology.
Conclusions: Scintigraphy is a well-tolerated non-invasive method of screening patients after esophagoplasty for estimation of long-term functional results. Gravity plays cardinal role in food passage through esophageal substitutes, though differences between different parts of GI tract do exist and should be attributed to motility. Esophageal substitution with jejunum or iso- or antipersistaltic gastric tubes has yielded best functional results.

Multi-stage tracheo-bronchial stenting and esophageal intubation for malignant respiratory tract and esophageal stricture

L. Kotsis, Zs. Pápai, K. Udud and E. Apáti *Thoracic Surgical Clinic and Bronchology of Korányi National Institute, H-1529 Budapest, Pihenõ u.1, Hungary*

Successive airway stenting and pull-through esophageal intubation for combined malignant respiratory tract and esophageal involvement is presented. From 1982 to 1998 239 patients underwent palliative esophageal intubation with a personally designed, composite tube at our service. In 118 instances the secondary esophageal strictures were induced by primary or recurrent bronchial tumour and mediastinal tumour or metastases. Among them four patients having a stenosing tracheal or bilateral main stem bronchial carcinoma has been managed by endoscopically introduced Dumon tracheal or bronchial stent followed by in second-stage, our esophageal tube insertion with a limited invasive surgical intubation technique. The overall hospital mortality was 9·3 per cent, without surgical or pulmonary complication in the above mentioned group of patients. Stenotic malignant tracheobronchial invasion was considered previously as a main contraindication of the palliative esophageal intubation. Recently, airway stenting combined with esophageal intubation may be considered an important step for extended, complex palliation in this high risk group of patients.

Quality of life and function of the esophageal substitute after esophagectomy and esophago-gastrostomy for esophageal cancer

G. Zaninotto, M. Costantini, A. Ruol, M. Anselmino, M. Renier, D. Molena, L. Nicoletti, D. Casara, S. Merigliano and E. Ancona
University of Padua, Istituto di Chir. Generale II, Italy

The recently proposed Gastrointestinal Quality of Life Index (GIQLI)[1] was used to evaluate the outcome of subtotal esophagectomy and gastric pull-up in 45 consecutive patients (33 male, 12 female, median age 64 years), at a median 13 months after surgery. All the patients were recurrence-free; patients with anastomotic stricture were excluded. The GIQLI was based on a questionnaire containing 36 questions, each of which was attributed a score from 0 (=always) to 4 (=never), regarding foregut symptoms (heartburn, regurgitation, dysphagia, belching), as well as physical, emotional, social and therapeutic aspects of post-operative life in these patients. A matched group of 71 healthy subjects (41 male, 30 female, median age 61 years) served as controls. A subset of 15 patients (7 male and 5 female, median age 64 years), 10 with moderate to severe foregut symptoms and five with no symptoms, was also evaluated by means of endoscopy with esophageal and gastric biopsies, supra-anastomotic esophageal pH- and bilirubin monitoring (Bilitec®), gastric bilirubin monitoring, biliary scintigraphy with ^{99m}Tc-HIDA and gastric emptying scan of a semi-solid meal.
Results: The overall GIQLI score did not differ between patients and controls (120·5, r. 92–142, vs 127, r. 86–143, P=ns); however, the partial 'symptom' score was lower in patients than in controls (16, r. 9–20, vs 20, r. 12–20, P<0·05): 17 out of the 45 patients (38 per cent) were considered as having moderate to severe foregut complaints (sympton score ≤15). The partial score regarding the patient's physical status also differed from controls (P<0·04), whereas the emotional, social and therapeutic scores were similar in patients and controls. In the group of patients who underwent functional evaluation, the presence of esophagitis, gastritis and abnormal acid gastro-esophageal reflux did not differ between symptomatic and asymptomatic patients, whereas the percentage time of the presence of bilirubin in the intrathoracic stomach and in the esophagus was significantly higher in symptomatic patients (P<0·01): in particular, an abnormal esophageal exposure to bilirubin was found in eight symptomatic patients, but only in one asymptomatic case (P<0·05). An abnormal ^{99m}Tc-HIDA biliary scintigraphy and delayed gastric emptying tended to be more frequent among symptomatic patients, though the difference did not reach statistical significance.
Conclusion: The overall quality of life in patients who undergo subtotal esophagectomy and intrathoracic esophagogastrostomy for esophageal cancer is good and does not differ from that of healthy controls, although physical performance is impaired and some foregut symptoms are recorded. These symptoms seem to be mainly related to the presence of bile reflux and, possibly, to abnormal gastric emptying.

Development of minimally invasive direct access surgical technology (MIDAST)

G.J. Jako *Boston University School of Medicine, 169 East Emerson Street, Melrose (Boston), MA 02176 USA*

The development of soft tissue microsurgery, precision minimally trauma surgery, endoscopic microsurgery and the application of video technology in 1960s and 1970s led to the new concept of Minimally Invasive Direct Access Surgical Technology (MIDAST) in the late 1980s. The MIDAST concept and instrumentation allows the surgeon to perform three dimensional-stereoscopic surgery now in eight subspecialities of surgery through a shorter incision. The incision is about 1/4–1/3 of the classic surgical incision. Special rectractor endoscope – JAKOSCOPE was developed from 1988 step by step until the final design was reached. Three sizes of Jakoscopes are available. High intensity fibre optics lighting provides brilliant visualization of the surgical area which is viewed by the surgeon's two eyes (binocular vision). Angled hand instruments have also been developed which give the surgeon better, direct access to work at the surgical site. He also has direct access for palpation and placing sutures or clips.

Modern versions of surgical stapling devices – the first surgical stapler was invented in 1907 by H. Hull in Budapest – are also useful for certain procedures. While the surgeon needs no video for the operation, an optimal specially developed video camera provides for demonstration and recording.

Most of the surgical procedures of MIDAST were developed in recent years experimentally and clinically by Hungarian surgeons. It has certain advantages over laparoscopic surgery such as expense, shorter operating time, no CO_2 gas insuflation needed. It is a real three dimensional approach which is easy to learn for an otherwise skillful surgeon.

By the turn of the century now, it is practised in general, cardiac, thoracic, vascular, pediatric, gynecological, urologic and orthopedic surgery.

Microlaparotomy cholecystectomy

I. Rozsos and J. Ferenzy *M. Kaposi Medical Centre and Hospital, Kaposvar, Hungary*

Starting in 1988, a new concept, surgical technique and instrumentation was developed to perform cholecystectomies through a 4 cm incision. The vertical midline incision is made at the base of the infrasternal triangle.

This minimally invasive direct access surgical technique (MIDAST) is comparable to the laparoscopic technique as far as the postoperative pain and ambulation but has more advantages.

For 1990 in unselected cases, all operations were started with a 4 cm microlaparotomy incision. Out of 2012 operations, 1861 cases (92·5 per cent), the 4 cm microlaparotomy incision was used. One hundred and forty-three cases (7·1 per cent) required modern minilaparotomy extending the incision up to 6 cm. The extended incision was required in cases of choledocholithotomies, repair of bilioenteric fistulas, anomalic location of the gallbladder, etc. In four cases (0·2 per cent), the incision was extended to 8 cm, i.e. classic minilaparotomy was performed. These included type II Mirizzi syndromes and sphincterolithotomy. Only four cases of 2012 required classic cholecystectomies through a modified longer than 8 cm incision. These cases included severe cystic artery bleeding and liver resection for gallbladder cancer.

The operated patients were grouped into three categories: 512 cases (25·5 per cent) simple; 855 cases (42·5 per cent) intermediate; 645 cases (32 per cent) obstructive cholecystitis. Three patients (0·014 per cent) died within 30 days after surgery. Ten patients (0·5 per cent) required reoperations, three for injury of the common duct, three bile leakage, three bleedings, one Schloffer tumour, one clip removal, one ileal intussusception. In 130 cases (6·5 per cent), stone was removed from the common duct through a 6 cm minilaparatomy incisions or in 31 patients (24 per cent of 130) through 4 cm microlaparotomy incisions.

Three hundred and forty patients (16·8 per cent) were classified as difficult surgery cases. The average operating time in the simple group 512 cases (25·5 per cent) was 18 minutes, in the intermediate group 855 cases (42·5 per cent) 35 minutes and in the obstructive cholecystitis group 645 cases (32 per cent) 30 minutes.

Minimal and direct access abdominal surgery with the 'Jako-endoscopic-retractor'

G. Fröschle, Zs. Király, R.A. Von Jako and G.J. Jako *University Hospital Hamburg Department of Surgery, Martinistr. 52 20246 Hamburg, Germany and Boston, University School of Medicine, USA*

In recent years, minimally invasive operations in abdominal surgery, due to laparoscopic techniques, has had a rapid development. A multi-purpose reactor system, the Jakoscope® developed by Jako provides an interesting alternative for minimal and direct access surgery without pneumoperitoneum. This instrumentation allows a direct access through 3–6 cm single incisions using fibre optic light.

During the past six months we used the Jakoscope® for several abdominal operations. We started first using it for cholecystectomies in previously operated patients (n=5) and two patients with contraindications for pneumoperitoneum. The mean operation time was 65 minutes (55 to 81) with success in all and the mean incision was 5 cm, intraoperatively measured. The average hospital stay was comparable to laparoscopic surgery as well as the average use of analgetics.

Encouraged through these results we operated on posterior rectopexy in two patients using 6 cm incisions. The average operation time was 63 minutes and the patients left the hospital after six days without problems and no anal prolapse.

With the rapid development of laparoscopic operating techniques other potentially minimal invasive methods have been neglected. Reducing operating times and analgesia, the cosmetic cut size and reduced hospitalization are positive results of the minimal and direct surgery with the described system. This new interesting surgical concept provides direct three-dimensional vision and palpation. The cuts are not longer than laparoscopic surgery when added. We are planning to operate a diverticulitis patient in the near future.

Aortoiliac reconstruction using minilaparotomy approach: technique and clinical results

G. Weber and J.G. Jako *1st Department of Surgery, University Medical School of Pécs and Boston University School of Medicine, MA, USA. H-7643 Pécs, Ifjúság u. 13, Hungary*

Aim: The large transperitoneal approaches used to the conventional aortoiliac reconstruction are accompanied with a relatively high postoperative morbidity and mortality rate (2 per cent to 5 per cent) even in patients who are good risks undergoing aortic surgery. This significant perioperative morbidity is partly caused by the major surgical trauma. To decrease the surgical stress on these patients the authors developed a less extensive procedure utilizing minilaparotomy and videoendoscopy.

Methods: From June 1993 through August 1997, patients undergoing surgery for aortoiliac occlusive disease were randomized comparing the minilaparotomy (ML) with conventional transperiotneal (CT) incision for aortic surgery. One hundred and nine patients participated in this trial, with 54 in the ML group and 55 in CT group. There were no significant differences between the groups in terms of age, sex or comorbid conditions.

Results: The incidence of intraoperative complications was similar for both groups. After surgery, nasogastric drainage was significantly (P=0·01) shorter, bowel movement and initiation of alimentation began earlier in ML group. Both groups of patients showed a significant decrease in vital capacity and forced exspiration volume postoperatively, but this depression was significantly higher (P=0·05) in CT group. The ML group also had significantly shorter stay in the intensive care unit (P=0·01) and the mean duration of the postoperative hospital stay was also significantly less (P=0·05). Generally, the patients operated by ML method during the postoperative recovery period required less analgesia, and expressed better 'overall satisfaction'. In long-term follow-up (mean: 31 months), there was no significant difference in survival rates between two groups.

Conclusions: The preliminary experiences proved that this method decreases surgical stress without endangering the safety of the patient during any point of operation and it may become the procedure of choice for selected patients with obstructive aorto-iliac disease.

inimal and direct access in thoracic diagnosis and surgery

Nabradi, R. von Jako, J. Wain and J. Boni *2nd Department of*
ɪrgery, University Medical School of Debrecen, Hungary.
ıssachusetts General Hospital and Harvard Medical School,
ston, MA, USA

troduction and methods: As an alternative to Video Assisted Thoracic rgery (VATS), which uses several small openings and two dimensional leo vision, we developed the direct access technique. Here we use a 5 cm single intercostal incision to view the lung and the thoracic struc-es. The surgeon has direct three dimensional viewing and access with dified standard instruments using the Jakoscope® retractor endoscope. gh-intensity lighting from a xenon light source with fibreoptics light ides provide brilliant illumination for diagnosis and surgery. Short doscopic types of instruments, clips, and stapling devices are also used.
tient material: In the past two years we performed 119 thoracic proce-res: 57 diagnostic and 62 therapeutic operations. These include thoracic npathectomy – 21 cases, pleural or lung biopsy – 57 cases, benign medi-inal tumour – five cases, mediastinal cyst and lung cyst – eight cases, nign lung tumour – five cases, recurring pneumothorax – 23 cases.
scussion: The Jakoscope® techology provides an excellent and less pensive alternative to Video Assisted Thoracic Surgery (VATS).

It also provides excellent and 'all around viewing' of the chest cavity d structures. Palpation, suturing, and ligature placing are simple proce-res with the Jakoscope®.

It allows quick entrance into the chest and simplifies procedures espe-lly in high risk patients. The short intercostal incision is less traumatic d cosmetically better than the standard thoracic incision. It can be plied in many different types of thoracic operations. The postoperative in is reduced compared to standard thoracic operations and hospitaliza-n is shortened. We had no operative mortality. The postoperative pain d ambulation is comparable to the thoracoscopic approach.

inimal and direct access endoscopic surgery in gynecology

Bodis, G. Jako, T. Lehoczky, T. Dyevich and R. von Jako
epartment of Gynecology, County Teaching Hospital, Pecs
niversity Medical School, Hungary. Boston University School of
edicine, 169 East Emseron St., Melrose (Boston), MA, 02176,
SA

e use of laparoscopic surgery for various gynecological procedures has creased during the past decade. In recent years we developed an alter-tive simpler and less expensive Minimally Invasive Direct Access rgical Technique (MIDAST^{tm}).

With this new concept and surgical technique the length of the lower dominal incision is decreased to 1/3–1/2. Minilaparotomy or mini-anenstiel incisions up to 6 cm in length or microlaparotomy incisions of m are used. The operation necessitates the use of a novel endoscopic ractor, Jakoscope® which has high-intensity illumination provided by non light source and fibreoptics wave guide. With this technology the rgeon has three dimensional-stereoscopic direct view of the operative e. It also provides direct access for palpation, suturing and cutting.

To simplify and improve precision for partial or total hysterectomy a w electrosurgical instrument GYNESNARE^{tm} was developed. It can be ed in mono or bipolar mode with the Erbotom Electrosurgical nerator. The MIDAST^{tm} has been used for the following operations in ble 1 and its advantages are shown in Table 2 and 3.

ble 1
inilaparotomy for gynecological operations:
ture of perforations of uterus
yomectomy
ysterectomy
Ovarian cystectomy
Ovarian wedge resection
Oophorectomy
Adnexectomy
Salpingectomy
Linear salpingotomy
Salpingostomatoplasty
Tubal resection and end-to-end anastomosis
Tubal sterilization
Appendectomy

Table 2
Advantages of minilaparotomy vs laparoscopy:
Shorter operative time
Extensive (commonly disposable) equipment
No CO_2 insufflation
Easy organ removing
Costs are reduced

Table 3
Advantages of minilaparotomy vs laparotomy
Shorter hospital stay
Shorter recovery period
Less pain for the patient
Cosmetic advantage
Costs are reduced

In addition, with this technique, urogynaecological operations such as Burch procedures can be performed.

Howard-Jako technique for minimally invasive direct access surgery (MIDAS) for anterior lumbar interbody spine fusion

D. Howard, H. Haynes and R. von Jako *Melrose-Wakefield*
Hospital, Department of Surgery, 585 Leabenon Street, Melrose
(Boston), MA, 02176, USA

With the use of the Jakoscope®, a very versatile mini-lap approach to the anterior spine is now available. The Jakoscope does not have the limitations of the other retractor systems in that it can be used for all levels of the anterior lumbar spine, it supplies its own light source and does not rely on other fixation devices as K-wires or Knowles pins. Excellent direct exposure is obtained at the L4–5 and L5–S1 levels, accounting for the majority of spinal instability and degenerative disk problems of the lumbar spine. A 4–6 cm incision can be used in a transverse Pfannenstiel manor or it can be placed vertical, either in a paramedian or midline position. This approach can be used either trans-abdominally or retroperitoneally. By retroperitoneal dissection, the entire procedure can be carried out avoiding direct contact with the abdominal contents with less risk of ileus, CO_2 absorption and secondary complications from CO_2 insufflation. The Jakoscope allows for excellent direct visualization of the great vessels for ease in mobilization and management of bleeding. It is easily able to incorporate the use of the microscope or for the use of optical loupes or a micro-video camera for teaching and demonstration.

In 30 cases, the average length of stay is 2·5 days postoperative. With the exception of two vascular injuries, we have had no major complications. Minor complications of atelectasis, ileus, EUTI, etc., remain the same as, or less than those that are encountered with conventional laparotomy. The operating time for a typical inter-body fusion is under two hours, with an additional 30–40 minutes for each additional level.

We believe that the direct open mini-laparotomy approach to the lumbar spine through a 4–6 cm incision allows for a safer surgical procedure than the laparoscopic approach with an equal or shorter length of stay and a greatly reduced cost to the patient. Having performed both laparoscopic and open retroperitoneal Jakoscope approaches, we feel the Jakoscope is far superior and unlikely to be replaced with the laparoscopic procedure.

Use of a new fat pad sparing minimally invasive incision and a fibreoptic retractor (Jakoscope) in the treatment of cruciate ligament and chondral injuries

G. Kish, L. Hangody and R. von Jako *Saint George Medical,*
545 Lafayette Road, Suite P, Portsmouth, New Hampshire
03801 USA Uzsoki Hospital, Mexiko ut. Budapest, Hungary.
Atlantis Surgical, Boston, MA, USA

Aim: Cruciate ligament reconstruction is common, and chondral surface replacement is being popularized. These procedures are technically demanding and problems continue to plague the surgeon. Many of these problems have to do with visualization and the pitfalls with arthroscopic approaches. In an effort to diminish these complications and reduce the operative time a Minimally Invasive Direct Access Surgical (MIDAST) approach to Cruciate Ligament Reconstruction and Chondral Transplantation has been developed.
Material and methods: Based on cadaver studies ongoing since January 1996, clinical trials with the new approach and instruments were begun in July 1997 involving 15 patients to date. By use of a randomized, controlled study, ACL, PCL and mosaicplasty have been done by the MIDAST (Minimally Invasive Direct Access Surgery) technique, arthoscopic one incision technique and by conventional Arthrotomy. Comparison in terms of anesthesia time, total incision length, need for a second surgeon, operative equipment required, and operative and postoperative complications, and postoperative morbidity were documented.
Results: The preliminary results of the three groups involving 15 patients has shown that those patients operated by the MIDAST technique had shorter operating room times and the length of hospitalization compared equally to the arthoscopic group when comparing similar procedures. Postoperative complications in each group were too few to reach any statistical significance.
Conclusions: Our preliminary conclusions are that this technique of fat-pad sparing incision and operative and postoperative complications and is equal to arthoscopic postoperative recovery. All in all, fewer instruments are needed, and the procedures are more cost effective surgery

Split-liver transplantation

One of the major challenges facing organ transplanatation is the current shortage of donors. Successful outcome after liver transplantation has led to an increasing number of adults and children being assessed and transplanted. Initially, paediatric transplantation was limited by the lack of size-matched donors, particularly for children under 5 years of age, but the development of reduced-size liver transplants resolved this problem. In the technique of reduced-size liver transplantation a whole liver is reduced to left lobe or left lateral segment (LLS) and used for a small recipient, usually a child; the residual liver lobe is discarded. Liver reduction techniques led to a fall in the number of children awaiting liver transplantation, but it placed adult recipients at a disadvantage as grafts are withdrawn from the adult donor pool. This has led to increasing competition between adult and paediatric centres for the 'young' donors most appropriate for liver reduction. A further source of grafts is from living related donors; living related transplantation was introduced to transplant small children from a donor parent. However, such transplantation requires a healthy relative to undergo major surgery and it is performed most widely in countries lacking cadaveric transplant programmes. The development of split-liver transplantation (SLT)[1], in which the donor liver is divided into two grafts, LLS for a child and a right lobe for an adult, increases the number of grafts for children without affecting the adult donor pool.

The initial results of SLT were disappointing in comparison to those obtained from whole and reduced grafts, with a reported graft and patient survival of 50 and 65 per cent respectively[2–4]. Because of this, the procedure was not considered suitable for elective patients. However, collective data from Europe[5] have shown that the initial poor results were due primarily to the selection of poor-risk recipients. More recent reports have described graft and patient survival rates comparable to those achieved with whole- and reduced-size liver transplantation in good-risk recipients[6,7]. Other problems encountered in earlier cases included a high incidence of primary non-function (4–5 per cent)[4,8]. This was due to prolonged bench surgery leading to rewarming injury and prolonged cold ischaemia for the second grafts. The authors' own experience[7] is, if good-quality organs are selected, that the incidence of primary non-function or dysfunction can be reduced to a very low level even in the presence of prolonged cold ischaemia. The export of one of the grafts to another institution is developing; this relieves pressure on a hospital's resources. As results improve it should become more commonplace.

Biliary complications have long been recognized as a significant problem in SLT, affecting 5–25 per cent of recipients[3,4,8]. The increased biliary complications in the right lobe graft have been due to excessive dissection of the common bile duct during bench surgery, rendering it ischaemic. Anomalous biliary drainage may also be a cause. Biliary complications may be reduced by the use of cholangiography to identify anomalous biliary anatomy and by avoiding unnecessary dissection of the common bile duct during bench dissection. The authors prefer to divide the left duct away from the bifurcation close to the division into segment II and III ducts and the routine use of a T tube in the right lobe grafts. An increased incidence of vascular complications has been reported in SLT, with a hepatic artery thrombosis rate of 9–25 per cent, possibly due to the use of grafts with short vessels. The question of which vessels should be assigned to each graft is unresolved, with some centres keeping the main trunk of the hepatic artery and portal vein with the right graft[6,8]. We prefer to allocate the main trunk of vessels to the LLS graft, as our policy is to accept the liver for a child who receives a LLS and only to use the right lobe if splitting is anatomically feasible. Experience suggests that lengthening of the right portal vein is rarely necessary and, although the right hepatic artery may need lengthening, neither arterial nor venous thrombosis has been observed in right lobe grafts. Back-table angiography is performed routinely in some centres[6,8], but the only indication seems to be to identify whether arterial anomalies from the left gastric or superior mesenteric arteries are the sole or accessory supply to left or right grafts.

The technique of *in situ* liver splitting[5,9] has recently been described, with good short-term results from centres with previous experience of *ex vivo* SLT. The improved survival figures may be attributable to increased surgical experience of splitting livers and better patient selection. However, there are important advantages to this procedure over *ex vivo* dissection which include the avoidance of prolonged bench surgery, sharing of organs by two centres with short cold ischaemic times to both grafts, and perfect haemostasis during the donor operation leading to reduced blood loss during the recipient operation. The major drawback to the procedure is the increased operating time in the donor hospital. The transplant community has tried to minimize the inconvenience caused to donor hospitals by modifying surgical techniques to shorten donor operating time[10]. We believe that extended operations may have a potentially negative effect on other members of multiorgan retrieval teams and hospitals, thereby defeating the purpose of splitting livers. Experience has shown, if good quality organs are selected, that results comparable to *in situ* splitting can be achieved with the *ex vivo* technique.

So far 75 split-liver transplants have been performed in this centre, with a patient survival of 85 per cent at a median follow-up of 14 months. With a large paediatric programme performing approximately 55 paediatric liver transplants a year, our policy is to split any good quality organ. The index recipient is usually a child requiring elective or emergency transplantation. The LLS graft produced by SLT is similar to that of a reduced-size graft with no additional risk to the child; the right lobe is used for elective patients with chronic liver disease. Conversely, an adult patient requiring urgent transplantation would receive a whole graft and not part of a split liver. The only situation in which splitting may be performed in such unfavourable circumstances is if there are two urgent patients, one adult and one paediatric; such situations are rare.

SLT is often considered to have the potential of doubling the number of grafts available. Currently the limiting factor is the number of children suitable for LLS engraftment and this accounts for about 10 per cent of all recipients. A proportion of these will receive whole size-matched paediatric grafts. Thus the potential of SLT is only to increase the donor pool by about 5 per cent, unless the technique is developed further to permit the transplantation of two adults. Even so, the 5 per cent increase may have an impact on waiting list mortality rate. The success of SLT in our programme has reduced the need for living related transplantation. Although we have an active living related programme, within the UK only 15 such transplants have been performed, with a patient and graft survival of 93 per cent and no donor death. Our current policy is to place children being assessed for living related transplantation on the cadaveric waiting list; over the past year four children were transplanted with a split-liver graft before the assessment was completed. The waiting time for small paediatric recipients has significantly decreased.

SLT represents a significant source of paediatric liver grafts without compromising the adult donor pool, provided the right lobe graft is used in relatively stable patients. However, it remains a demanding surgical procedure that should be performed in centres with extensive experience of liver anatomy and reduced-size liver transplantation, and with resources that can cope with the extra demands placed on the institution.

Announcement

The British Journal of Surgery, Scientific Surgery and the World Wide Web

We are pleased to announce a new initiative in this month's *British Journal of Surgery*. As part of the Journal's commitment to the practice of surgery based on scientific evidence, we will publish a page devoted to an index of randomized clinical trials in surgery. The Scientific Surgery page will appear monthly and identify all clinical randomized trials collected from 50 English language journals.

Each month the references will be added to a database on *The British Journal of Surgery* website. It is hoped this easily accessible Scientific Surgery Archive will eventually be of value to surgeons seeking sound information for the practice of clinical surgery or references for surgical papers. Details about how to access the website can be found on the Scientific Surgery page at the back of this Journal.

The Editors welcome comments and suggestions about this Scientific Surgery Initiative and about *The British Journal of Surgery* website.

Review

Metabolic response to severe injury

A. G. HILL and G. L. HILL

University Department of Surgery, Auckland Hospital, Auckland, New Zealand
Correspondence to: Professor G. L. Hill

Background Severe injury is associated with a complex sequence of metabolic events. The accurate quantification of these changes and a developing understanding of their aetiology has been the product of much work by researchers over the past 60 years. An understanding of these phenomena is vital to the practising surgeon because of the plethora of new metabolic modulators threatening to become part of clinical practice.
Methods This review describes the clinical picture of the metabolic response to severe injury and then outlines modern understanding of the underlying processes.
Results and conclusion The need for further research before introduction of new technologies is emphasized.

The body's response to injury is complex, integrated, and designed to restore homeostasis and heal the wound as rapidly as possible. In the vast majority of cases this set of responses is remarkably well coordinated and quickly restores the person to health. However, in a small group of patients (those with multiple injury) the response is in excess of that required, given modern intensive care techniques; it is frankly damaging. This group of patients might benefit from metabolic manipulation, but manipulation of the host response to injury has suffered much from simplistic approaches to what has become increasingly recognized as a very complex system. This review attempts to integrate knowledge in this area in the hope that it will be useful to those caring for these patients.

Clinical picture

Ebb and flow phases of Cuthbertson

Ashen facies, a thready pulse and cold clammy extremities are the most obvious clinical manifestations of the metabolic response soon after injury. The picture changes dramatically after adequate resuscitation. The patient warms up, cardiac output increases and the surgical team relaxes. It was the Scottish biochemist David Cuthbertson who, nearly 70 years ago, first described these two distinct phases after injury[1,2]. He gave the cold clammy phase the apt title 'ebb phase' and called the warm pink phase the 'flow phase'. The distinct characteristics of these two phases are set out in *Table 1*.

Table 1 The ebb and the flow phases of Cuthbertson

Ebb phase	Flow phase
Hypometabolic	Hypermetabolic
Low core temperature	Raised core temperature
Decreased energy expenditure	Increased energy expenditure
Normal glucose production	Increased glucose production
Mild protein catabolism	Profound protein catabolism
Raised blood glucose	Raised or normal blood glucose
Raised catecholamines	Raised or normal catecholamines
Raised glucocorticoids	Raised or normal glucocorticoids
Low insulin	Raised insulin
Raised glucagon	Raised or normal glucagon
Low cardiac output	Increased cardiac output
Poor tissue perfusion	Normal tissue perfusion
Patient cold and clammy	Patient warm and pink
Preresuscitation phase	Recovery phase

Phase of haemodynamic instability

After severe injury there is usually a period of haemodynamic instability which lasts about 3 days. This is a time during which the flow phase is a staccato affair as it struggles to break from the grip of the ebb phase. The patient requires both colloids and inotropes in addition to crystalloids over this period but, once the flow phase has fully developed, colloid infusion and increasing inotropic support are no longer needed. A recent study in this department of ten critically injured patients (median Injury Severity Score of 35) found a positive fluid balance of about 4·7 litres on average over this period and in most of the patients clinical oedema was obvious[3].

Hypermetabolic or flow phase

The swollen patient, now stable and well perfused, enters the flow phase during which profound metabolic interchanges occur. The patient is weaned from the respirator and, with inotropes withdrawn, leaves the intensive care unit for the ward. Diuresis occurs and the body-weight falls steadily (approximately 0·6 kg/day), pretrauma weight being reached around the end of the second week. If all goes well discharge home may be expected 4–7 weeks later. Now, especially if suffering the after-effects of head and skeletal injury, although wasted, weak and lacking volition, the family will note substantial improvements as each week progresses.

Metabolic picture

All illness results in oxidation of body protein and fat, and an increased hydration of the fat-free body mass. Such changes have recently been quantified in a group of

Paper accepted 15 January 1998

critically injured patients within the context of modern trauma care[3]. Nearly one-fifth of the body's store of protein is lost over the first 3 weeks, most during the first 10 days. Two-thirds of the loss is from skeletal muscle. It is this loss of skeletal muscle protein which leads to problems with respiratory function and subsequent weaning from ventilators, and it is one of the major factors influencing morbidity and mortality following injury[4]. If adequate energy intake is administered fat is not burned as fuel and body fat stores are not diminished. The study also showed that the 5 litres or so of resuscitation fluids retained early on are mainly located in the extracellular space. As recovery progresses this excess extracellular fluid is excreted. Although intracellular fluid also steadily decreases over time this decrease is broadly in proportion to the loss of other cellular constituents.

Hypermetabolism

All injured patients have a rise in resting energy expenditure of 5–60 per cent depending on the magnitude of injury. In the multiply injured patients described above there was an increasing energy expenditure, maximal at about 10 days after injury, as the flow phase developed. This increased energy expenditure signifies increased oxygen consumption by the body to support the massive exchanges of substrate between organs that occur as a part of the metabolic response.

Altered protein metabolism

The loss of protein from the body after injury was first recognized more than 60 years ago. Cuthbertson in 1932[1] described a group of patients who had sustained orthopaedic trauma, and noted an enhanced loss of nitrogen (16 per cent of protein is nitrogen) from the body. This negative nitrogen balance was maximal from day 2 to day 8 after the injury and lasted for up to 1 month. Cuthbertson concluded that the increased nitrogen came from breakdown of skeletal muscle protein, suggesting that it was 'to meet the exigencies of the metabolism of the recuperative process'[2]. This concept was later developed by Moore: 'it is our conviction that the destruction of lean tissue mass has as its purpose the provision of raw materials for wound healing'[2,5].

In prolonged critical illness the initial response is the breakdown of liver and muscle glycogen stores. Following rapid exhaustion of glycogen, new glucose is derived from gluconeogenic precursors which arise primarily from skeletal muscle protein. This is accompanied by a blunting of the normal adaptive ketoaemic response to starvation[6]. Important products of this protein breakdown in skeletal muscle are the amino acids alanine and glutamine. Glutamine is the most abundant free amino acid in the body, and its intracellular concentration falls profoundly after trauma and may remain low for many weeks[7]. Glutamine's importance lies in the fact that it is a prime fuel for the enterocyte and the cells of the immune system; it is thus important for gut barrier function and immunity[8,9]. While there is an increase in protein catabolism in critical illness there is a corresponding, but lesser, increase in protein anabolism[10]. The net result, however, is catabolic.

Altered fuel metabolism

Fat constitutes the major fuel reserve of the body. The critically ill patient has a high turnover rate of free fatty acid (FFA) and glycerol, which is suppressed during glucose infusion. Re-esterification of FFA occurs at an accelerated rate and FFA oxidation is increased, leading to the conclusion that fat is a major fuel in the traumatized patient[10], but this applies only if nutritional support containing adequate energy intake has not been given[3].

Glucose is the principal fuel supplying the relatively hypoxic injured tissues and the cells within them. Lactate is produced and released into the circulation for transport back to the liver for the further production of glucose (Cori cycle). Most of the new glucose is produced by the liver not only from lactate but also from alanine and other glucogenic amino acids. Although this endogenous glucose production can be suppressed in the normal subject by the infusion of glucose, in the injured patient this occurs to a limited extent only[10].

Altered water metabolism

Forty-five years ago Dr Francis Moore of Harvard Medical School, using isotopic dilution studies, described changes in water metabolism in injury[5]. Body water changes closely parallel body-weight changes and are largely accounted for by changes in extracellular water[3]. In younger patients this excess is excreted readily but older patients take twice as long to excrete this fluid[11]. This may contribute to a poorer outcome in the elderly from critical illness.

Initiators and propagators of the metabolic response

Traditionally the metabolic response to injury has been viewed as a neuroendocrine reflex arc, with pain and hypovolaemia stimulating the brain to coordinate a massive outpouring of counter-regulatory hormones which produce glycogenolysis, fat catabolism and protein breakdown. Recently this view has been challenged with the discovery of a huge array of mediators and with developing research into the recovery or flow phase of injury.

Role of the neuroendocrine response

Campbell and associates[12] and Ingle *et al.*[13] in the late 1940s and early 1950s investigated the role of glucocorticoids in protein metabolism, demonstrating that in adrenalectomized rats the loss of nitrogen observed following femoral shaft fracture in control rats is obliterated. Egdahl[14] demonstrated convincingly the importance of the peripheral nervous system in the early endocrine response to injury. He disconnected a limb from the body of an anaesthetized dog, leaving only the sciatic nerve and femoral artery and vein. Trauma to the enervated portion of this limb evoked glucocorticoid secretion. The nerve was then divided and repeated trauma failed to produce a rise in glucocorticoids. Infusion of the counter-regulatory hormones (catecholamines, glucocorticoids and glucagon as a triple hormone infusion) into normal human volunteers, in concentrations seen in the ebb phase, results in metabolic alterations qualitatively similar to those observed in injured patients[15]. Importantly, however, the nitrogen loss noted with this combination of hormones is modest and not associated with net skeletal muscle protein breakdown.

Bessey and Lowe[16] showed that by using somatostatin to block insulin secretion, as observed in the ebb phase of injury, a triple hormone infusion results in much larger nitrogen losses. They also showed that excessive nitrogen loss in the first 48 h of an insulin suppressive triple hormone infusion, compared with a standard triple hormone infusion, is not associated with increases in forearm amino acid nitrogen efflux (the forearm being used because its predominant metabolically active tissue is skeletal muscle). This suggests that the nitrogen originates elsewhere, probably from splanchnic tissues as the gut has one of the highest protein turnover rates in the body. Catecholamines appear to be important for altered fat metabolism. The increased rates of lipolysis and triglyceride turnover observed in the injured patient are probably due to increased catecholamine activity, β-activity promoting lipolysis and α-activity leading to inhibition of FFA turnover[17].

Extension of the neuroendocrine response into the recovery phase may lead to a prolonged convalescence. Elderly patients, who appear to have a normal metabolic response to injury often suffer from this[18,19]; after hip fracture they have a prolonged increase in plasma cortisol which may partly account for an extended loss of body protein and poor recovery[19].

Role of cytokines

Significant objections to the role of the neuroendocrine axis as the sole mediator of the metabolic derangement after injury were previously voiced by Cuthbertson. He noted that the neuroendocrine response to surgery was limited to 24 h, whereas the increased nitrogen output attained its maximum several days later during the recovery phase[20].

In addition to efferent nervous signals, circulating factors also initiate the metabolic response to injury. Drucker *et al.*[21] studied paraplegic patients with chronic decubitus ulcers, noting that an operation on a denervated area results in alterations in glucose metabolism. Wilmore *et al.*[23] later showed that patients with burn injury and spinal transection maintain a hypermetabolic response, as do similar patients in whom the afferent nervous signals are interrupted by local, regional or general anaesthesia. They also showed that only in patients with brain death was the hypermetabolic response to burn injury diminished. In 1893 Coley[23] demonstrated the regression of tumours injected with bacterial toxins. The cause and significance of this phenomenon remained obscure until 1985 when Cerami's group purified the cytokine tumour necrosis factor (TNF)/cachectin[24,25]. Independent work by others led to purification of interleukin (IL) 1, a key mediator of the hepatic acute-phase response and an endogenous pyrogen.

TNF infused into humans and animals induced a net catabolic state by mediating increased catabolism at the level of specific tissues, by causing anorexia, and by activating the hypothalamic–pituitary–adrenal axis[26–29]. The metabolic effects after TNF administration are dose related and with increasing dose include enhanced energy expenditure, increased hepatic gluconeogenesis, increased whole body protein breakdown, activation of the hypothalamic–pituitary–adrenal axis and increased whole body lipolysis; these are all features of the metabolic response to injury. In even larger doses TNF triggers potentially catastrophic tissue injury and lethal shock[30,31].

Like TNF, IL-1 in lower concentrations is beneficial; it stimulates defence mechanisms[32]. However, in higher concentrations, it stimulates the production of a number of mediators which cause other biological effects, including fever, hypotension, inflammation and proteolysis, possibly via the lysosomal energy–ubiquitin-dependent proteolytic pathway[33–36].

IL-1 and TNF may have a synergistic effect in producing the metabolic manifestations seen after injury or infection, as infusing the two cytokines together in rabbits has more effect than either of the cytokines alone on energy substrate metabolism[37]. However, three pieces of evidence argue against systemic cytokine release accounting for all of the metabolic changes seen after injury. First, cytokines have not been consistently found in the bloodstream of injured patients (with the exception of IL-6). Second, the effects of intravenously administered cytokines, although profound in the short term, are not sustained and tend to diminish quickly. Third, cytokines do not appear to have direct effects on muscle protein breakdown.

Attention therefore has recently turned to the role of cytokines at the tissue level, such as the liver and the central nervous system. IL-1 and IL-6 have been detected in the cerebrospinal fluid of head-injured patients, and IL-1 may be able to cross the blood–brain barrier[38–40]. TNF receptors are present in murine brain and TNF is produced by rat astrocytes *in vitro*[41,42]. TNF and IL-1 are found in the cerebrospinal fluid of children with meningitis and in experimental meningitis, TNF is found in the cerebrospinal fluid but not in the serum, suggesting that it can be produced by the brain[43–46]. There is also an extensive network of IL-1 nerve fibres enervating the hypothalamus and recent work has demonstrated that chronic central nervous system exposure to IL-1 produces catabolism in the rat that is not mediated by glucocorticoids[47]. After thermal injury a very early rise in liver and lung IL-1 is observed[48] and infusions of IL-1 by differing routes produce different effects[34], suggesting that IL-1 is produced in, and acts on, different organs to produce many of the responses seen after injury[49].

The role of IL-6, which may be an important mediator in the ebb phase, is probably to stimulate the liver to produce acute-phase proteins. This may account for some of the nitrogen loss which occurs in severe injury[50]. Although very high levels of IL-6 correlate with death after trauma, IL-6 may only be a marker of severity of injury (like C-reactive protein) rather than a major causal agent[51,52].

Although the relative contributions of cytokines and counter-regulatory hormones are unclear, they appear to have synergistic effects. When IL-1 is induced by etiocholanolone injection and counter-regulatory hormones are infused simultaneously, there is a substantial increase in protein breakdown compared with either stimulus given alone[53]. The roles of IL-1 receptor antagonists, soluble IL-1 and TNF receptors remain to be clarified, although it seems likely that they act to prevent the deleterious effects of unchecked production of TNF and IL-1[49].

Role of the wound

The site of injury probably also plays an important role. Neutrophils and macrophages are attracted to the site and, in addition to producing cytokines, they generate important mediators which act locally on the wound and distally on organs such as the liver, gut and skeletal muscle. These mediators include platelet activating factor, oxygen free radicals, nitric oxide and arachidonic acid metabolites. They act both directly on cells and indirectly by altering regional blood flow[54–57]. The complement cascade is also involved as complement is activated after injury[58,59] and is able to stimulate monocytes to produce IL-1[60,61]. At present the role of the wound is uncertain but what is clear is that the wound releases a large number of mediators with the potential for metabolic activity. Whether or not they act in any more than a paracrine fashion remains to be shown.

Role of cellular dehydration

According to Haussinger *et al.*[62], the profound loss of body protein that occurs in injured patients is triggered and maintained by cell shrinkage secondary to cellular dehydration. Finn and the Auckland group[63] measured the total body content of protein, potassium and water and its compartments in nine patients with blunt multiple trauma. They found that cells lose water in quantities greater than would be expected from protein losses. Haussinger's work was mainly with isolated cells and these new clinical data support the hypothesis that cellular dehydration is a trigger for protein catabolism. It has, however, been argued by some that the relationship between cellular dehydration and proteolysis is not so clear cut, and that cell shrinkage is merely an epiphenomenon. Concomitant with these changes in cellular hydration are changes in cellular energetics[64].

Role of the gut

The gut has been considered 'the motor of multiple organ failure'. This concept has been supported by a number of animal (but only a few human) studies, demonstrating translocation of bacterial products across the gastrointesinal tract after shock and other injuries[65]. Severe injury is thought to lead to increased intestinal permeability which is related to a systemic inflammatory response[66,67]. In this model, changes in intestinal flora, coupled with impairment of the normal barrier function of the gastrointestinal tract, allow the bowel to serve as a reservoir of pathogens. From this reservoir they or their products may enter the portal and systemic circulations, thereby fuelling the ongoing metabolic process either directly or via activation of macrophages to produce cytokines in either the liver or the mesenteric nodes[68,69]. The alteration in gut permeability is probably related to glutamine deficiency in stress states. Glutamine is an important fuel for enterocytes and in the presence of glutamine deficiency the gut mucosa atrophies and a breakdown of gut-barrier function occurs[70].

Although there is a plethora of animal data supporting this hypothesis it has remained difficult to demonstrate after human injury[71]. In addition, much of the work in humans has been done in the ebb phase of injury, which is unlikely to be the ideal time for such a study. Because of this, a role for bacterial translocation in the pathogenesis of the metabolic response to severe injury cannot be entirely discounted, but further work is needed.

Role of ischaemia–reperfusion

The role of the ebb phase is probably to set the stage for the more profound metabolic alterations of the recovery phase. The ebb phase acts as an ischaemia–reperfusion event, especially for the gut. Reductions in regional intestinal blood flow result from stimuli such as hypovolaemia, acidaemia and hypercarbia, via hormonally and neurally mediated splanchnic vasoconstriction[72]. With resuscitation there is secretion of the counter-regulatory hormones, a decrease in insulin and the generation of

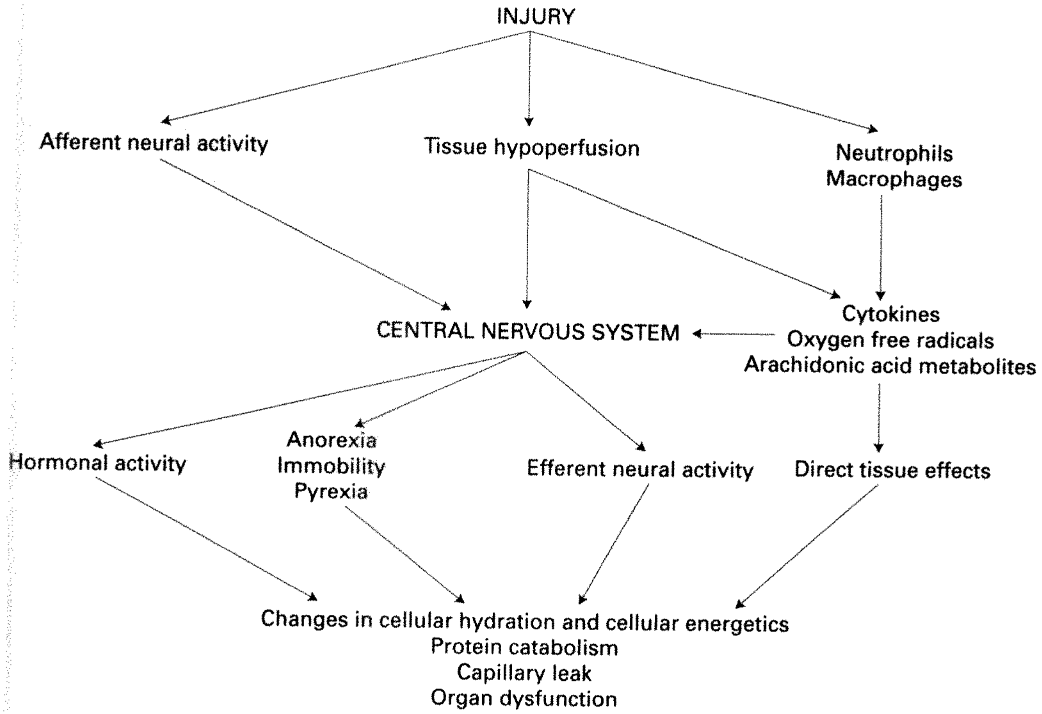

Fig. 1 Injury produces afferent neural activity, hypoperfusion and immune activation. These, in turn, set up a cascade of events coordinated by the central nervous system and at the level of individual tissues such as the liver, gut and skeletal muscle. These events are mediated by a complex array of neutrophil and macrophage products. The end results are changes in cellular energetics and hydration, lysis of skeletal muscle and visceral protein, capillary leakage into the lungs and subcutaneous tissues, and organ dysfunction

mediators, such as oxygen free radicals, eicosanoids, complement, nitric oxide and cytokines (TNF, IL-1, IL-6, IL-8), and the activation of neutrophils. With the restoration of tissue perfusion, especially in extreme injury involving contaminated and damaged tissue, these mediators, in association with anorexia, pyrexia, and immobility, act to cause the skeletal muscle protein breakdown characteristic of the flow phase. This protein breakdown is critical in slowing recovery from injury.

Role of immobility

Bedrest leads to a catabolic state characterized by muscle weakness, muscular atrophy and a negative nitrogen balance[73]. The protein loss, however, is only a fraction of that observed in severe injury; it is probably due to decreased whole body protein synthesis as protein breakdown is not a feature[74,75]. Glucagon and cortisol levels are raised, which may explain the insulin resistance noted in this situation, but there are no changes in catecholamines or growth hormone[76].

Future avenues for metabolic response modification

The metabolic response to injury is not a simple system. Further work is needed on the compartmentalization of cytokines and other signal proteins[49]. The critical role of the central nervous system needs to be elucidated. The roles of the gut and the wound itself remain unclear and further investigation is required in these areas in the human.

Conclusion

The response to injury may conveniently be divided into an ebb (resuscitative) phase and a flow (recovery) phase. The metabolic perturbations of the resuscitative phase are best understood as a reflex arc of the peripheral nervous system and the immune system, using cytokines as the afferent limb, the central nervous system as the co-ordinator, and the counter-regulatory hormones as the efferent effectors. These effectors, along with alterations in tissue oxygenation, free radical generation, cytokine production and other mediators, set the stage for the profound metabolic changes of the recovery phase (*Fig. 1*). Cytokines are produced in injured states which are capable of stimulating neuroendocrine activity, hepatic acute-phase protein production, anorexia, fever and net protein catabolism; these are all features of the metabolic response to injury. It is likely that they are key players in this response and that their effect is mediated via the hypothalamus. Also important are efferent central nervous system activity, immobility, oxygen free radicals, arachidonic acid metabolites, the complement cascade and altered gut permeability following the ischaemia–reperfusion insult of injury.

Therapeutic intervention with anticytokines, epidural anaesthesia, growth hormone and nutritional modification has shown some promise in arresting the massive losses of protein observed after severe injury, and has led to better understanding of the underlying mechanisms involved. However, much work is required to find the correct combinations for use in individual patients. Much effort is also required to achieve a better understanding of the complex alterations in body chemistry that occur after injury. Understanding these phenomena may lead to a future in which critically ill patients will be treated with specific therapies directed at conservation of body protein and healing of the injury.

Review

Diet, reflux and the development of squamous cell carcinoma of the oesophagus in Africa

A. M. SAMMON and D. ALDERSON

University Department of Surgery, University of Bristol, Bristol Royal Infirmary, Bristol BS2 8HW, UK
Correspondence to: Mr A. M. Sammon

Background Squamous cancer of the oesophagus has reached epidemic proportions in Africa in the past few decades. There are many known associations but as yet no well established theory of causation.

Methods Relevant literature was found by manual review of appropriate journals and literature, Medline searches and cross-referencing. Published theories of causation of endemic cancer of the oesophagus were assessed in the light of available evidence. A hypothesis based on that evidence was formulated.

Results and conclusion A predominantly maize-based diet is high in linoleic acid, a precursor for gastric prostaglandin synthesis. In combination with low intake of other fatty acids and riboflavin, high levels of prostaglandin E_2 are produced in gastric mucosa, leading to reduced gastric acid secretion, relaxation of the pylorus and a reduction in lower oesophageal sphincter pressure. These events result in combined reflux of duodenal and gastric juices low in acidity into the oesophagus. Resulting dysplasia strongly predisposes to local squamous carcinogenesis. This is now a fertile area for research, which may open the way for preventive action.

Squamous cell cancer (SCC) of the oesophagus is a major cause of death worldwide. It is particularly common in the Linxian region of China, the Caspian littoral region, Iran and Southern Africa, and has been described in these areas as endemic. A wide variety of factors have shown an association with endemic SCC. Common factors include a diet based on either maize or wheat, a poverty of minerals and vitamins in the diet, and little fresh fruit and vegetable consumption[1]. Tobacco use has a clear association in Africa[2–4]. Some specific local carcinogens have been postulated such as alcoholic concoctions in South Africa[5] and opium in Iran[6]. However, these have not had a causal link proven and ongoing search for the predominant carcinogen in each region has thrown up many possible but no probable candidates.

Postulated causal mechanisms

Postulated causal mechanisms for endemic areas include those involving direct insult or local carcinogenesis by a single agent and multifactorial hypotheses including (1) direct insult plus carcinogen, (2) direct insult plus carcinogen and nutritional deficiency, and (3) carcinogen plus nutritional deficiency.

Single agents

Direct insult. Maize-based beer and alcohol in general have been proposed as major factors in South Africa[7,8]. There is no consistent association, however, between alcohol and SCC in endemic areas[2,4]. A significant proportion of patients with SCC in endemic areas do not consume alcohol[2,3].

Carcinogen. Tobacco carcinogenesis is widely advocated as an adequate single cause. The evidence that tobacco is a carcinogen involved in endemic SCC aetiology is overwhelming[2,3]. As with alcohol, many patients with SCC do not use tobacco at all[2,3], ruling out tobacco as the single cause of high incidence.

Fungal mycotoxins[9] and viral infection[10,11] both have associations with SCC, and have been put forward as carcinogenic agents, but the evidence remains circumstantial.

An unidentified carcinogen in the full Transkei diet was postulated by Purchase *et al.*[12], based on experimental studies in rats. A higher incidence of cancer of the oesophagus was evident on a full Transkei diet compared with a restricted diet. Particular suspicion was cast on wild vegetables including *Solanum nigrum* (garden nightshade). Nitrosamines in food have also been suggested but, again, the evidence is circumstantial[13].

Multifactorial mechanisms

Direct insult plus carcinogen. Tobacco plus alcohol is a well documented causal combination[14–16]. Alcohol may act as an oesophageal irritant, a solvent for the carcinogens of tobacco, or as a true co-carcinogen. Van Rensburg[1] and Wynder and Stellman[17] believe its effect is to cause or accentuate dietary deficiencies of minerals and vitamins. The combination of tobacco and alcohol is well established in non-endemic areas as the major causal association of SCC, although not in endemic areas.

Direct insult plus carcinogen plus nutritional deficiency. Several studies support this hypothesis. Warwick and Harington[18] reviewed the evidence in Transkei and suggested that a combination of local

---

Paper accepted 21 January 1998

alkalinization from tobacco use, combined with nutritional deficiency (particularly pellagra) and other physical insults (including excess alcohol and plant emetics), are responsible for SCC, with or without the effects of carcinogens in local tobacco. Bradshaw and Schonland[19] cite oesophageal insults, including smoking, alcohol and emetics, combined with a general state of malnutrition and an unidentified carcinogen.

Morris and Price[20] hypothesized that papillomavirus was an essential part of the carcinogenic process, causing a 'glycogenic acanthosis', a process favoured by a reduction in immune competence in malnutrition. Smoking, alcohol, aflatoxins and malnutrition would all contribute to successive stages in the progression to dysplasia and carcinoma.

Carcinogen plus nutritional deficiency. Van Rensburg[1,2,21] has argued consistently that the staple diets of all endemic areas are deficient in a range of micronutrients, particularly zinc, magnesium, riboflavin and nicotinic acid, predisposing to carcinogenesis by agents as yet not clearly identified.

The concept that dietary deficiency is the major problem has been challenged by the finding that SCC is a disease of people of some education and means[2]. A case–control study in Transkei[3] found no association with a history of pellagra, the main deficiency disease associated with a maize diet. In Africa, cancer of the oesophagus is nevertheless closely associated with the use of maize as a staple dietary element. The deficiencies of such a diet have been studied repeatedly, but the effects of the constituents of maize have been spared close examination.

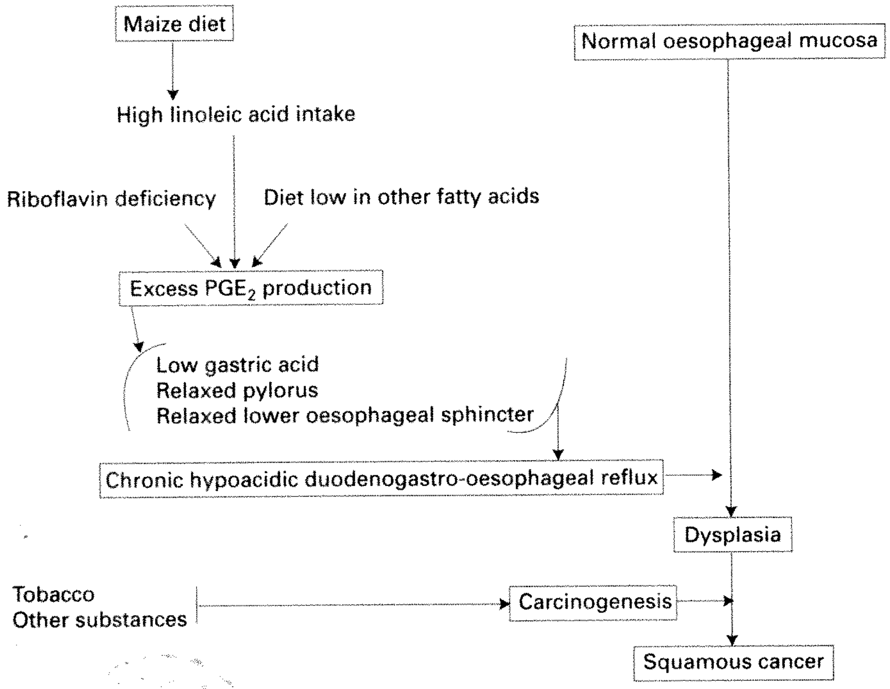
A two-stage hypothesis of carcinogenesis is consistent with the available data: (1) predisposition by a diet-associated low-acidity duodenogastro-oesophageal reflux (DGOR) and (2) carcinogenesis by a variety of agents.

Steps of a new hypothesis

1. A high level of linoleic acid ingestion is associated with increased prostaglandin E_2 production in the stomach. Other dietary factors increase this effect (Fig. 1)

SCC has followed some decades after the adoption of maize as the dietary staple in east Africa, mirroring its geographical spread. Throughout the world, all areas of high risk for SCC use maize and/or wheat as staples[1]. The risk rises with increasing consumption of maize by the individual[2,22]. Van Rensburg[1] described the association in Africa as fitting with 'prolonged exposure to a predominantly corn diet dating from childhood'. Maize is rich in linoleic acid and very low in other essential fatty acids. A case–control study in Natal showed that the more frequently bought maize meal is consumed, the higher the risk of cancer of the oesophagus[2]. The relative risk of daily as against weekly buying of maize meal was 5·7 : 1. In the community studied, three maize forms are consumed, whole kernels, stamped (broken) maize and maize meal. Whole kernels are poorly and slowly digested, releasing little oil in the stomach. Stamped maize has the oil-containing husk removed and provides no linoleic acid at all. Maize meal is the preparation which provides all its linoleic acid to the stomach in an easily digestible form. A similar significant association with the consumption of maize meal was found in a high-incidence area of Italy[22].

Linoleic acid is a prostaglandin precursor. Wistar rats fed a long-term diet high in linoleic acid develop a sustained increase in prostaglandin (PG) E_2 levels in the stomach[23]. PGE_2 production is promoted by absence in the diet of other fatty acids[24] which cause competitive inhibition. In African endemic areas for SCC, there may be little dietary fat apart from that in maize; dietary fat from sources other than maize is negatively associated with SCC[2,3].



Maize diet
Normal oesophageal mucosa
High linoleic acid intake
Riboflavin deficiency
Diet low in other fatty acids
Excess PGE2 production
Low gastric acid
Relaxed pylorus
Relaxed lower oesophageal sphincter
Chronic hypoacidic duodenogastro-oesophageal reflux
Dysplasia
Tobacco
Other substances
Carcinogenesis
Squamous cancer

Fig. 1 A diet based on maize with deficiency of other elements will lead to high prostaglandin (PG) E_2 production and a chronic low-acid oesophageal reflux, with consequent predisposition to cancer

Riboflavin deficiency results in an increased biosynthesis of PGE_2[25] through a deficiency of glutathione peroxidase, which is dependent on the sulfhydryl group provided by riboflavin. Riboflavin deficiency is a factor common to the major endemic areas of the world for SCC[26,27]. Maize diets contain inadequate riboflavin and riboflavin content is further reduced by any refinement[1]. Riboflavin deficiency has been implicated in the early stages of oesophageal cell proliferation and dysplasia[28].

The scenario in which a high level of PGE_2 will be produced is a diet rich in linoleic acid, low in other fatty acids and deficient in riboflavin. A diet heavily dependent on maize creates exactly this combination and will promote a high level of gastric PGE_2 production.

2. PGE_2 inhibits gastric acid secretion and reduces the tone of the pyloric and lower oesophageal sphincters, resulting in a chronic hypochlorhydric DGOR

PGE_2 causes a reduction in lower oesophageal[29] and pyloric sphincter pressures[30,31], with a reduction in both basal and stimulated gastric acid output[23]. The logical result is increased oesophageal reflux of gastroduodenal fluid of reduced acidity. Heartburn is very common in Transkei, affecting 60 per cent of a group of healthy people studied. Symptomatic regurgitation of fluid identified as bile was present in 75 per cent of sufferers. Heartburn can be abolished by aspirin[32].

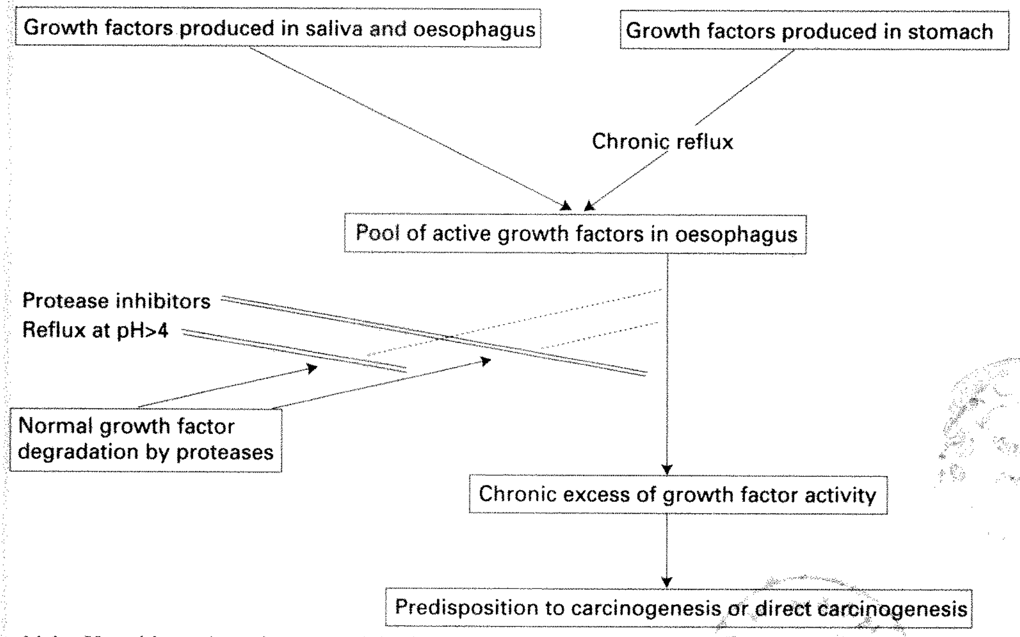
3. Chronic low-acidity DGOR predisposes to squamous carcinogenesis

With reduced concentrations of gastric acid, any refluxate into the oesophagus has a higher pH than normal. This predisposes to the development of carcinoma. Seto *et al.*[33] subjected three groups of rats to oesophageal carcinogens: gastrectomized rats with regurgitation of duodenal contents, gastrectomized rats without regurgitation, and healthy controls. All the animals in the group with duodenal regurgitation developed cancers which were exclusively squamous; none of the other groups developed any cancers. Oesophagitis and severe dysplasia were present in association with the cancer-bearing areas.

Partial gastrectomy is a known risk factor for delayed (15–20 years) squamous cancer of the oesophagus. About 8 per cent of patients with squamous cancer of the oesophagus will have had a previous gastrectomy[34], the risk increasing with time since gastrectomy. Lower oesophageal sphincter function is often impaired[35] and acid production is reduced or abolished after major gastric resection. Colin-Jones *et al.*[36] reported a relative risk of 2·3 for cancer of the oesophagus at 5–7 years after cimetidine use, but did not state whether this was predominantly SCC or adenocarcinoma. Enteral PGE_2 has been shown to promote oesophageal carcinogenesis in rats[37].

A possible mechanism for the carcinogenic effect of a chronic hypoacidic DGOR is shown in *Fig. 2*. Epidermal growth factor (EGF) and transforming growth factor (TGF) α are products of salivary glands, oesophageal mucosa and stomach. Luminal overexpression as well as high binding activity have been implicated in proliferative drive and carcinogenesis in the gastrointestinal tract[38–41] and elsewhere[42,43]. Growth factors are partially or wholly inactivated by trypsin[44] and by pepsin if the pH is below 4[45]. Interference with normal activity of these two proteases will allow growth factors to be more active (longer or at higher levels) in the oesophagus. A reflux of duodenogastric juice at a pH of 4 or above will contain no active pepsin, but will contain active EGF and TGF-α, and will not inactivate salivary growth factors.

It is of great interest that constituents of staple diets of east and southern Africa include beans and pumpkin, which contain trypsin inhibitors[46,47]. *Solanum nigrum*, which is used as a vegetable in some parts of Africa[48], contains a pepsin inhibitor[49] and has a significant association with SCC in Transkei[3]. Oesophagitis and squamous dysplasia are strongly associated with endemic SCC in Africa and beyond[50,51]. Oesophagitis has been



Growth factors produced in saliva and oesophagus
Growth factors produced in stomach
Chronic reflux
Pool of active growth factors in oesophagus
Protease inhibitors
Reflux at pH>4
Normal growth factor degradation by proteases
Chronic excess of growth factor activity
Predisposition to carcinogenesis or direct carcinogenesis

Fig. 2 Reflux of a high pH and ingestion of protease inhibitors ensure excess growth factor activity in the oesophagus

proposed as a precursor lesion[50], but more recent evidence suggests that the true precursor lesion is the concomitant dysplasia, with significant risk only from moderate dysplastic change[52].

Tobacco has a known association with SCC in Africa, and its use brings with it a relative risk of up to 5·99 compared with non-smokers[2,3]. It has been noted, however, that other racial groups in South Africa use much more tobacco than Africans, yet have a markedly lower incidence of oesophageal cancer, implying that other factors must be important. The oesophagus may be predisposed to carcinogenesis from a variety of sources.

Discussion

Any theory of causation needs to explain the consistently reported associations of endemic SCC of the oesophagus with (1) heavy dependence on a maize-based diet over a very long term, (2) slow rise in incidence, (3) relative poverty and (4) tobacco, at a high-risk level.

The rise of SCC has followed decades after the introduction of maize. It takes a considerable time to supplant another staple or group of staples and for maize to become almost the only constituent of the diet, then finally for maize meal to become the predominant form ingested. The finding that SCC is a disease of people of some education and means[2] can be accounted for by poorer people eating more stamped maize and kernels, and the richer, transitional group eating more maize meal.

Tobacco has a well proven record of association with a high relative risk. It seems to be a more potent carcinogen in the endemic situation than in non-endemic populations. Studies from endemic areas have, however, shown a significant percentage of non-smokers among victims of SCC[2,3]. This implies that tobacco is working synergistically or on a predisposed mucosa; it may be only one of a number of carcinogens to which the oesophagus is exposed. In addition, cigarette smoking encourages gastro-oesophageal reflux[53].

The association of SCC with alcohol, which has been well demonstrated in non-endemic areas, has never been established in endemic areas. Low-dose alcohol stimulates acid secretion[54] and also causes gastro-oesophageal reflux[55]. It is possible that alcohol has no additive effect to the factors already operating to cause a low-acid reflux. The dominance of squamous cancer fits in well with the finding that acid reflux favours columnar differentiation/regeneration[56–59]. The process of differentiation is affected by growth factors[60–62] and the local oesophageal environment of low-acid reflux may affect this activity.

The steps of a hypothesis have been described, with supporting evidence linking these elements to endemic areas in Africa. While the steps have been based on the African situation, there are many features common to other endemic areas, which share some of the pathways described. The major implication of this hypothesis is that preventive measures are possible, even in medically underserved areas which suffer the endemic form of this disease.

A further issue raised is that a chronic low-acid reflux may increase squamous carcinogenesis. The increasing availability of acid- and pepsin-suppressive therapies, which can create a hypochlorhydric gastro-oesophageal refluxate low in protease, could increase the risk of squamous carcinogenesis with long-term usage, particularly in African populations.

In the Western world, the possible links between diet, tobacco and chronic drug therapies deserve wider attention. This is particularly so in the light of dramatic rises in the incidence of adenocarcinoma and its known association with Barrett's metaplasia as a consequence of chronic gastro-oesophageal reflux[63–65]. It is intriguing that duodenogastric reflux may also play a part in the development of Barrett's metaplasia, adding a further similarity between SCC and adenocarcinoma aetiologies. This is also worthy of careful dietary study.

Review

Metachronous colorectal cancers

O. FAJOBI, C.-Y. YIU, S. B. SEN-GUPTA and P. B. BOULOS

Department of Surgery, University College London Medical School, Whittington Hospital, Highgate Hill, London N19 5NF, UK

Background Up to 9 per cent of patients who undergo resection for colorectal cancer develop metachronous cancers. There is no consensus on the detection and management of such cancers.

Methods The literature was reviewed exhaustively regarding the incidence, clinical characteristics, detection, treatment and molecular genetics of metachronous colorectal cancers. This was based on a Medline search from 1966 to December 1997 for articles on metachronous colorectal cancers. A manual search was also performed on references quoted in these articles. All publications relevant to this study were included.

Results Although the underlying causes for metachronous colorectal cancers are yet to be elucidated, risk factors for the disease have been identified. These include the presence of synchronous polyps or cancers, a history of metachronous cancers, and hereditary non-polyposis colorectal cancer (HNPCC).

Conclusion Preoperative colonoscopy and postoperative colonoscopic surveillance are essential in identifying patients at risk of metachronous colorectal cancer. A total colectomy and ileorectal anastomosis should be considered for some patients, certainly for those with HNPCC.

Definition

A primary large bowel cancer which occurs at any time after the surgical achievement of a 'clean' colorectum (i.e. free of all neoplasms) is termed metachronous[1–4]. The malignancy must be unequivocally new and not a recurrence or metastatic deposit of the initial lesion[5].

There is little consensus regarding the distinction between truly metachronous and missed synchronous large bowel cancers. Neoplasms occurring after a set interval from the index cancer are described as 'metachronous' while those discovered before this time are termed 'missed synchronous'. Studies have used various intervals (6 months[4,6–8], 1 year[9,10], 2 years[11–15] and 3 years[16,17]) from the initial cancer to differentiate the two conditions.

It is essential that synchronous cancers and polyps are identified before surgery. Universal colonoscopy is the optimal method but logistic, financial and manpower implications limit its routine use. A selective policy is therefore more practical[18]. In 35 per cent of patients the index cancer may not admit the colonoscope; peroperative colonoscopy should be considered[16] or a clean colon established within 3–6 months of surgery[11,19].

Incidence

A lifelong risk of developing metachronous colorectal cancer exists in all patients who have undergone large bowel resection for malignancy[2,11,15,20]. The risk is believed to have a small but definite increase with length of survival after the first operation for colorectal cancer[1]. The incidence of metachronous colorectal cancer is estimated at 0·6–9 per cent[11,12,21–23]. This variation in incidence is a reflection of the fact that the number of new large bowel primaries detected is directly proportional to the length of follow-up[11,15]. The annual rise in incidence with length of survival following index surgery is estimated at 0·35 per cent per annum[15]. The cumulative incidence rises to 30 per cent after 41 years of follow-up[11].

Paper accepted 4 February 1998

Evolution of metachronous colorectal cancers

The time it takes a metachronous colorectal cancer to develop after surgery for the index tumour varies widely. Some authors estimate that between 20 and 46 per cent of metachronous colorectal cancers are diagnosed within 2 years of the primary operation[1,14]. Agrez *et al.*[4] reported that 50 per cent of metachronous cancers occur within 5·5 years, a finding confirmed by Kaibara *et al.*[9]. A varying average interval to detection of metachronous colorectal cancer is reported in the literature: 3·5 years[13], 7 years[15], 11 years[7], 12 years[24] and as late as 41 years into follow-up[11].

Although the adenoma to carcinoma sequence is thought to take about 5–15 years[25,26], it is not known whether this applies to the development of metachronous colorectal cancer. Metachronous and synchronous tumours are features of hereditary non-polyposis colorectal cancer (HNPCC) syndrome which is characterized by a genetic predisposition to colorectal cancer (usually on the right side) at an early age, and extracolonic malignancies of the endometrium, ovary, stomach, small intestine, biliary tract, ureter, renal pelvis and pancreas[27,28]. Jass *et al.*[29] believe that adenomas in patients with HNPCC are more likely to be villous in nature, with high-grade dysplasia, and are more aggressive than sporadic adenomas. Certainly metachronous colorectal cancers arising from mutations in HNPCC genes may develop within 2–5 years of a negative colonoscopic screening examination[30]. The time taken for the adenoma to carcinoma sequence is probably determined by the precise genetic mutations involved[31].

Characteristics of metachronous colorectal cancers

Characteristics of the index cancer

It is believed that there is a tendency for metachronous large bowel cancers to arise in patients with index neoplasms of a more favourable Dukes stage, histological grade and prognosis[1,11]. In the Mayo Clinic series[4] of 62 metachronous cancers, 79 per cent of index lesions had no nodal involvement. However, in a large Japanese series[9] only 5·4 per cent of index tumours were classifiable as early among those who later developed metachronous colorectal cancer. Rennert *et al.*[23] and Heald[32] believe the more favourable staging of index cancers is simply a reflection of mortality selection bias.

Dukes stage of metachronous colorectal cancers

The Dukes stage and histological differentiation of metachronous colorectal cancers at diagnosis are no worse than for single tumours. However, some studies have reported generally more favourable tumours[14,23,32–34]. Cali *et al.*[15] state that metachronous colorectal cancers are more likely to be local disease with a lower propensity to distant metastasis than index cancers. This is disputed by others [4,16,24,35,36].

Distribution

Metachronous cancers may occur anywhere in the large bowel. While in many series there is a predominance of right-sided lesions[4,15,23,37,38], in others the distribution is even throughout the colorectum[14,39]. Svendsen *et al.*[40] noted that the relative risk of developing metachronous colorectal cancer was highest in the right colon and diminished towards the rectum. Only one study has reported a predominance of left-sided metachronous cancers[35] and two reports have suggested a similar distribution to single cancers[6,32]. When considering the distribution of metachronous lesions it should be appreciated that up to 60 per cent of colorectal cancers are found below the descending–sigmoid colon junction[41]. It is conceivable that the greater numbers of left colonic resections may increase the likelihood of subsequent metachronous cancers developing in the right colon. Furthermore, right-sided metachronous cancers, especially in a young cohort of patients, may represent unidentified cases of HNPCC syndrome[40].

Aggressiveness of metachronous cancers

Four papers report a greater aggressiveness of metachronous cancer compared with the index lesion[4,23,24,42]. However, many authors emphasize that the second colorectal cancer exhibits the same (certainly no worse) behaviour as the index cancers[14,23,32,33].

Risk factors for metachronous colorectal cancer

Previous colorectal cancer

Where a synchronous cancer is resected along with the index tumour, the cumulative risk of developing a subsequent metachronous neoplasm rises from 3·5 per cent for a single cancer to more than 8 per cent for two cancers[32]. Following excision of a metachronous colorectal cancer, the risk of further metachronous cancers is also increased[12]. Agrez *et al.*[4] reported third subsequent cancers in seven (11 per cent) of 62 patients with metachronous cancer.

Polyps

The risk of metachronous colorectal cancer is double in those with synchronous polyps associated with the primary cancer[1,7,11,43]. Luchtefeld *et al.*[44] reported a 71 per cent incidence of synchronous or interval adenomatous polyps with metachronous colorectal cancers. The incidence quoted in the St Mark's series[45] was 60 per cent and in the Mayo clinic series[4] 40 per cent. A 6·5 per cent frequency of metachronous large bowel cancer in those with synchronous polyps associated with the index cancer compared with 3·4 per cent in those without polyps was demonstrated by Chu *et al.*[36]. Moreover, patients with synchronous polyps less than 30 cm from the index lesion are more likely to develop metachronous adenomatous polyps, compared with those with polyps more distant from the index lesion[46].

Multiple polyps are associated with a higher risk of metachronous colorectal cancer than single polyps[6,39]. The number of polyps is larger with metachronous than with synchronous cancers[39,47–49] and in late, compared with early, metachronous cancers[14]. Over 50 per cent of metachronous cancers are associated with polyps of the tubular adenoma variety; about 10 per cent occur with villous adenomas[32]. The impact of repeated polypectomy on the subsequent occurrence of metachronous colorectal cancer remains to be evaluated[50].

Hereditary non-polyposis colorectal cancer

A propensity for metachronous and synchronous colorectal cancers with a predilection for the proximal colon and development of cancer at an early age are well recognized characteristics of HNPCC[83], a wide spectrum cancer susceptibility syndrome inherited as an autosomal dominant trait with a high penetrance of around 90 per cent[51]. Diagnosis is based on minimal criteria (the Amsterdam criteria) recommended by the International Collaborative Group in HNPCC[52]. These are (1) at least three relatives with histologically verified colorectal cancer, one of whom must be a first-degree relative of the other two; (2) at least two generations affected; and (3) at least one of the cases of colorectal cancer must be diagnosed before the age of 50 years.

Age

Several authors have reported a younger age at first colorectal cancer for those who subsequently develop another large bowel tumour[7,11,24]. In a group of patients with colorectal cancer under 40 years of age, the calculated risk of developing a metachronous colorectal cancer was 16–29 times greater than that of developing a primary cancer[40]. The authors[40] suggested that metachronous colorectal cancer in young patients may be an expression of the HNPCC syndrome. Indeed, in most series the age at diagnosis of the first tumour is comparable to that of single cancers[23] and the patients with metachronous cancer are generally older[6,23,53]. To date, younger age for index cancer is not a prognostic factor for metachronous cancer, but it is of diagnostic value with respect to HNPCC.

Sex

Most studies report no sex difference in metachronous colorectal cancer[2,23,24,54]. Sex has no known influence on the risk of developing a metachronous colorectal cancer[40].

Race

Only one study has considered the question of race, comparing Caucasians with American blacks; no firm conclusions were drawn[23].

Detecting metachronous colorectal cancers

Some studies have reported that regular follow-up and surveillance for metachronous cancer have resulted in the detection of early cancers with a greater potential for resectability[1,13,35]. While Enker and Dragacevic[35] were able to show a higher yield of asymptomatic and early lesions in those followed up for metachronous cancer than in those without follow-up, others have not found a significant difference in the number of curative resections in these groups[55].

Gerdes[56] advocated surveillance at intervals of 2 years for metachronous adenomas, whereas Spigelman[57] endorsed a single colonoscopy to exclude synchronous lesions and subsequent colonoscopic surveillance at intervals of 3 years only in those who are found to have adenomatous polyps.

Treatment of metachronous colorectal cancer

Metachronous colorectal cancers are usually suitable for further curative surgery. An operability of 61 per cent in a very young cohort of patients[8] and a curability rate of 81 per cent[9,39] have been reported. Only 5 per cent in a Japanese series[9] and 6 per cent in a series from St Mark's Hospital, London[45] were deemed inoperable.

Several authors suggest extensive resection for the prevention and treatment of metachronous cancer[33,35,36,42,58,59]. The alternative option of a conventional resection with regular examination of the colon is deemed appropriate[1,32,39,60,61]. Synchronous malignancy in different lymph drainage areas seems a justifiable indication for total colectomy with ileorectal anastomosis, whether at the time of treatment of the index or the metachronous cancer[24,62]. The potential benefit of a radical resection needs to be weighed against a significant morbidity and mortality rate. An individualized approach tailored to suit each patient should be adopted.

While total colectomy eliminates the need for colonoscopic surveillance, vigilance in examining the rectum is still required[63]. Of 17 HNPCC-related patients with colorectal cancer treated by total colectomy, four developed rectal metachronous tumours[64].

Survival

Survival from metachronous colorectal cancer appears not to differ from that associated with single cancers[11]. Stage for stage the prognosis for index and metachronous cancers is largely the same[4,8,11]. The 5-year survival rate after radical resection for multiple cancers in the St Mark's Hospital series was 66 per cent[45], compared with 66·5 per cent in the Japanese series[9] and around 50 per cent in most other reports[2,4,36,39]. The lowest reported survival figure is 20 per cent[14]. The main influence on survival is the stage at diagnosis of the metachronous cancer[23]. Early asymptomatic detection, therefore, offers a potential for improved outcome[35,55,65].

Advances in molecular biology and metachronous colorectal cancer

Individuals with metachronous large bowel cancer show evidence of genetic instability in the cancer, compared with sporadic cancers[53]. Genetic instability can be demonstrated by the accumulation of numerous genetic alterations, particularly in simple repeated non-coding sequences known as microsatellite DNA[71,72]. This phenotype is known as microsatellite instability (MIN) or replication error, and is a characteristic of 92 per cent of cancers from patients with HNPCC[73].

Genetic predisposition to colorectal cancer in HNPCC is due to inherited mutations in genes that control DNA mismatch repair. This DNA repair system serves to correct mistakes that may arise in DNA during its replication[74]. So far, inherited mutations have been identified in four DNA mismatch repair genes (*hMSH2*[66–68], *hMLH1*[70], *hPMS1*[69] and *hPMS2*[69]). Other genes, such as *GTBP*[75], which are involved in the mismatch repair pathway are known.

Thibodeau *et al.*[71] described type I mutations (instability at multiple loci) and type II mutations (instability at one or two loci) in colorectal cancers of the proximal colon. The degree of MIN tends to be very high in cancers from patients with HNPCC[73]; almost every microsatellite locus tested shows instability. Work with cell lines has shown that mutations in *GTBP* result in a low level of MIN[76].

Between 6·5 per cent[77] and 28 per cent[71] of sporadic cancers show MIN, and somatic mutations in the DNA mismatch repair genes have been identified in some of these cancers[78]. However germline mutations in the mismatch repair genes have been found in apparently sporadic colorectal cancers that show MIN[79]. Some reports suggests that MIN-positive sporadic cancers have a high level of instability[79] while others conclude that the level may be low[80].

It may be that the variable degree of MIN is due to different mutations in the DNA mismatch repair genes. So, although MIN appears to be a good indicator of mutation in the DNA mismatch repair genes, there is as yet no correlation between particular mutations and clinical phenotype[73]. In patients with metachronous colorectal cancer in whom instability was detected in the primary cancer, it was also detected in the metachronous cancer[53]. Similarly, when the index cancer did not show instability, neither did the metachronous cancer. The role of MIN as an indicator of metachronous colorectal cancer is under investigation. One study[53] affirmed its value while another did not[81]. A recent study[82] has confirmed that colonoscopic biopsies may be used for MIN analysis. Preoperative information about MIN status may have a role in assessing the risk of developing metachronous colorectal cancer and in the planning of the extent of surgical resection.

Conclusion

It is essential that the colon is scrupulously examined visually before operation for synchronous lesions and that appropriate surgical management is defined. When this is technically not feasible, for instance because of an obstructing carcinoma, a good quality double-contrast enema is an option, provided a postoperative colonoscopy is scheduled. When synchronous lesions are in the vicinity of the index cancer, conventional radical resection followed by regular colonoscopic surveillance is the accepted practice. For distant synchronous lesions, therapeutic endoscopy is a useful adjunct although, for large polyps or carcinomas or rapidly recurring metachronous lesions, a total colectomy and ileorectal anastomosis should be considered seriously in selected patients with a satisfactory sphincter mechanism. This radical approach is a safe option in those with established evidence, based on family history or genetic testing, of the HNPCC syndrome.

Digest

For this quarter's digest, Professor Christian Herfarth and Dr Thomas Lehnert have selected the best from the October to December 1997 issues of *Der Chirurg*. A digest for the BJS for the same period, written by Mr Colin Johnson, appears in the German journal.

This quarter's digest reviews articles addressing multiple trauma (four articles) and minimally invasive techniques in orthopaedic surgery (four articles) in recognition of the Annual Meeting of the German Society of Trauma Surgery, while a series of seven articles has been commissioned to provide a comprehensive overview of currently applied techniques in inguinal hernia surgery. In his editorial Shumpelick[1] takes a critical look at aggressive marketing and operations designed to suit all types of inguinal hernias. He calls for a problem-oriented approach for which Shouldice repair, preferably under local anaesthesia, should provide a reliable and minimally invasive repair for most inguinal hernias, primary or recurrent. Implantation of alloplastic material should be reserved only for very large hernias.

Carcinoma of the pancreas

Cancer of the head of the pancreas is traditionally treated by Whipple's partial pancreatoduodenectomy, if complete macroscopic tumour removal appears feasible. The operation carries postoperative sequelae which are partly related to loss of pyloric function and duodenal transit. Theoretically this may be overcome by pylorus-preserving partial pancreatoduodenectomy. The operation has proven useful for patients with chronic pancreatitis, but its applicability and long-term results in patients with ductal pancreatic cancer have been studied only in a few patients. Further arguments in favour of pylorus preservation are reduced operating time and blood loss, while concerns exist regarding radicality of local tumour resection.

The group from Ulm[2] presents their experience with 130 patients with ductal carcinoma of the pancreas treated between May 1990 and April 1995. A standard Kausch–Whipple operation was performed in 61 patients and 69 patients had a pylorus-preserving partial pancreatoduodenectomy. Data were collected prospectively, although this was not a randomized study. The distribution of men and women was similar for both groups and median age was 59 years (Whipple) and 61 years (pylorus-preserving operation). Mean(s.d.) operating times were longer for standard Whipple's procedure (405(60) min) compared with 360(35) min for pylorus preservation ($P < 0.001$). Intraoperative blood loss was a median of 3·1 litres for Whipple's operation *versus* 2·2 litres for pylorus-preserving partial duodenopancreatectomy ($P < 0.001$) and the latter required fewer perioperative blood transfusions. The postoperative morbidity rate was identical at 39 per cent for both groups. Thirty-day mortality rates of 2 and 3 per cent respectively were also not significantly different between the groups. Return to a normal diet was somewhat slower in the group in which the pylorus was preserved, but overall no significant difference was observed when the two groups were compared. Histopathological evaluation indicated that in the pylorus-preservation group slightly more patients were stage I (35 *versus* 23 per cent) and fewer patients were stage III (59 *versus* 69 per cent), although lymphadenectomy yielded more lymph nodes in the pylorus-preservation group (mean(s.d.) 27(5) *versus* 20(4) lymph nodes per specimen in the Whipple group). Median survival for stage I pancreatic carcinoma was 32 months after Whipple's procedure and 36 months after pylorus-preserving partial pancreatoduodenectomy. In stage III survival was 10 and 11 months respectively. The authors conclude that pylorus-preserving partial pancreatoduodenectomy allows for radical lymphadenectomy and is similarly successful regarding oncological long-term results. It should not be used for tumours close to the pylorus or postpyloric duodenum, but appears to be advantageous for other locations of pancreatic cancer, as the operation is technically easier, speedier and causes less blood loss.

Intensive care jaundice

It is a well recognized phenomenon that many patients requiring intensive care treatment for severe disease or postoperative complications develop jaundice without apparent involvement of the liver or bile ducts in the initial disease process. Surgeons from Frankfurt have undertaken to document prospectively all patients admitted to their intensive care unit (ICU) between December 1991 and November 1992, in an attempt to quantify the incidence of postoperative jaundice and determine its prognostic significance[3]. Patients were admitted from the general, urological and cardiovascular surgical services as were trauma patients and those undergoing orofacial surgery. During a 12-month period a total of 1572 patients were recorded. Patients undergoing operative treatment for or with pre-existing diseases of the liver, bile ducts or pancreas were excluded, leaving a total of 1275 patients for study. Standardized documentation used directly computer-readable forms to collect 2000 parameters per patient and day. Thus a total of 5·2 million individual parameters were obtained for statistical analysis.

Ninety-seven of 1275 patients admitted to the ICU developed a serum bilirubin level of 2 mg/dl or higher and were eligible for detailed analysis. Median length of stay of jaundiced patients was 15 (range 2–59) days compared with 2 (range 1–39) days in non-jaundiced patients. Twenty-eight (29 per cent) of 97 jaundiced patients died compared with 28 (2·4 per cent) of 1178 non-jaundiced patients. When several parameters related to disease severity such as septic organ failure score, multiple organ failure score, positive end-expiratory pressure ventilation, central venous pressure, low systolic arterial pressure (less than 90 mmHg for more than 120 min) and others were compared between jaundiced and non-jaundiced patients the latter had significantly higher readings, but the Acute Physiology And Chronic Health Evaluation II score was not different between the two groups of patients. Maximum bilirubin levels and maximum daily increase in bilirubin levels were both inversely related to outcome.

Interestingly, raised liver enzyme levels were recorded with almost equal frequency in both groups. Hyperbilirubinaemia was most frequently observed in patients with multiple trauma (14 of 34 patients) and patients undergoing vascular surgery (13 of 105, 12 per cent). Overall mortality rate was higher in jaundiced patients, but calculation of predictive values, sensitivity and specificity revealed that postoperative intrahepatic cholestasis was not a reliable prognostic indicator.

Complications of minimally invasive surgery

Pneumoperitoneum and intraoperative reverse Trendelenburg positioning of patients undergoing minimally invasive surgery may cause hypercoagulability and peripheral venous stasis with a subsequently increased risk of venous thrombosis. Baca and associates[4] have performed a prospective randomized controlled trial to determine whether low-risk patients benefit from postoperative treatment with low molecular weight heparin. Patients were eligible for the study if they were scheduled for laparoscopic cholecystectomy or appendicectomy. Patients having more than three of the risk factors (Broca Index over 130, smokers, past history of venous thrombosis, use of oral contraceptives) were considered at increased risk for venous thrombosis and were excluded, as were patients having epidural anaesthesia. Patients in the treatment group received low molecular weight heparin once daily starting on the day of the operation for at least 6 days. Patients in the control group received physiotherapy and compression stockings as did patients in the treatment group, but not low molecular weight heparin. Endpoints of the study were clinical venous thrombosis or pulmonary embolism. Interim analysis was performed after 500 patients had been randomized.

A total of 719 patients were randomized from 33 hospitals. One patient was excluded because of incomplete documentation leaving 359 each in the treatment and control groups. Mean(s.d.) age was 48(15) years in the treatment group and 45(16) years in the control group. The majority of patients were female in both groups (75 per cent), and 85 per cent (control) and 93 per cent (treatment) of patients had cholecystectomy. All except two patients had general anaesthesia. A total of 23 patients were suspected to have developed either venous thrombosis or pulmonary embolism. Additional diagnostic procedures (duplex scan, phlebography) confirmed the diagnosis in only two patients. Both had received low molecular weight heparin. Fifteen of 718 patients required conversion to open surgery and three underwent reoperation. No significantly increased incidence of intraoperative or postoperative bleeding, wound haematoma or other complications was noted in the treatment group. Because the frequency of study events was lower than anticipated the review committee decided that it was unlikely that a significant difference would be detected and the study was closed prematurely after 719 patients had been admitted; the planned number was 1000 patients. The authors conclude that in a low-risk group of patients postoperative low molecular weight heparin is not warranted after limited minimal access cholecystectomy or appendicectomy.

Background The open subtotal cholecystectomy technique has simplified removal of the difficult gallbladder. Increasing laparoscopic experience has made laparoscopic subtotal cholecystectomy (LSC) a feasible option in patients with complicated acute or chronic cholecystitis.

Methods LSC was performed in 29 patients with severe inflammation or fibrosis of the gallbladder associated with gallstone disease over a 23-month period. These 29 patients (mean age 53 years; 22 women) constituted 8·5 per cent of the total number of laparoscopic cholecystectomies performed ($n = 340$) and 15·6 per cent of 186 patients with acute cholecystitis. Eighteen patients in the latter group underwent conversion to open cholecystectomy. The indications for LSC were acute cholecystitis/empyema ($n = 23$) and severe fibrosis ($n = 6$).

Results The cystic duct was either clipped before division ($n = 15$), sutured ($n = 2$) or ligated using an Endoloop ($n = 10$). In two patients the gallbladder bed was drained without isolating the cystic duct. The posterior wall of the gallbladder was left intact to avoid excessive bleeding or damage to bile ducts in the gallbladder bed. A suction drain was inserted in 14 cases. Median operating time was 73 (range 45–130) min. One patient died after operation from a myocardial infarction. Six patients had local complications (two haematomas, three bile leaks, one minor wound sepsis) and nine developed respiratory infections. Median hospital stay was 5 (range 2–28) days.

Conclusion LSC is a safe, relatively simple and definitive procedure allowing removal of a difficult gallbladder and reducing the need for open conversion or cholecystostomy in the majority of patients.

The risk of bile duct injury during a standard cholecystectomy is greatest while dissecting in Calot's triangle, particularly in the presence of severe inflammation or fibrosis of the gallbladder[1]. Open subtotal cholecystectomy which was described by this group in 1985[2] has proven to be a safe, simple and definitive procedure in this situation[3–5]. Increasing laparoscopic experience and sophisticated techniques have made laparoscopic subtotal cholecystectomy (LSC) a feasible option[6]. This study describes the technical aspects and evaluates the results of LSC in the management of complicated acute and chronic cholecystitis.

Patients and methods

Patients who underwent laparoscopic cholecystectomy during the 23-month period from January 1994 to November 1995 were studied. Subtotal cholecystectomy was performed only on patients with severe inflammatory or fibrotic changes in Calot's triangle. Preoperative biliary investigations included liver function tests and ultrasonography. Endoscopic retrograde cholangiopancreatography (ERCP) was performed on patients in whom common bile duct (CBD) stones or other bile duct disease was suspected because of symptoms (e.g. jaundice, pancreatitis), raised alkaline phosphatase and bilirubin levels or dilated CBD on ultrasonography.

Laparoscopic technique

A standard laparoscopic approach was used. After division of adhesions to the anterior surface of the gallbladder, the cystic duct–Hartmann's pouch junction was identified by blunt dissection using a suction–irrigation (hydrodissection) technique. When feasible, the cystic duct and artery were clipped or ligated and divided in the standard fashion (*Fig. 1*). If this was not possible, or in cases with stone impaction, the gallbladder was incised at the level of Hartmann's pouch and divided circumferentially (*Fig. 2a*) which then allowed prograde dissection and isolation of the cystic duct with an Endoloop (Ethicon, Edinburgh, UK) (*Fig. 2b*). When isolation of the cystic duct was not possible, a purse-string suture was inserted in Hartmann's pouch or, when there was no evidence of bile leak, the gallbladder bed was simply drained after subtotal removal of the gallbladder.

Subtotal removal of the gallbladder was performed when the gallbladder was entered inadvertently or excessive bleeding occurred because of difficulty in finding a plane of dissection between the gallbladder and liver bed. Excision of the gallbladder was performed using electrocoagulation (hook dissector or scissors) at the gallbladder–liver bed junction leaving the smallest possible strip of posterior gallbladder wall. Destruction of the residual gallbladder mucosa with electrocoagulation was optional. Great care was taken to remove all spilled stones using a 'spoon' forceps and to wash the peritoneal cavity with a suction–irrigation system.

Results

Twenty-nine patients underwent laparoscopic subtotal cholecystectomy during the 23-month period. Mean age

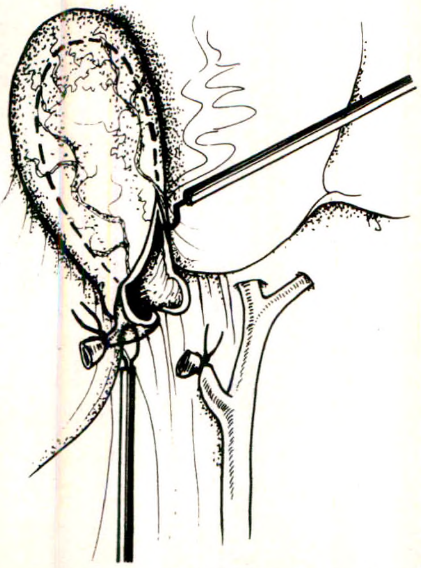

Fig. 1 Cystic duct ligated and divided in the standard fashion. Beginning of subtotal excision of the gallbladder

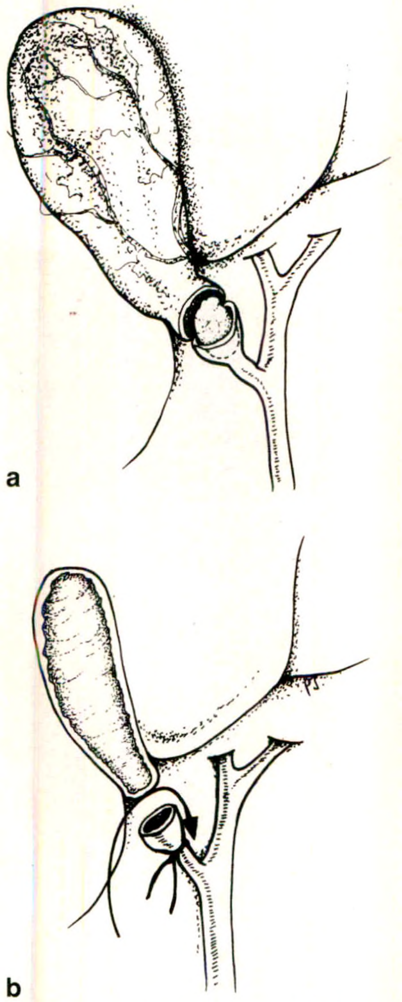

Fig. 2 **a** Gallbladder incised at the level of Hartmann's pouch with stone impaction. **b** Prograde dissection and isolation of cystic duct with Endoloop and subtotal removal of the gallbladder

was 53 (range 19–81) years; 22 were women. These patients constituted 8·5 per cent of the total number who underwent laparoscopic cholecystectomy ($n = 340$) and 15·6 per cent of patients with acute cholecystitis ($n = 186$). Twenty-four of the 340 patients underwent conversion to open cholecystectomy of whom 18 had acute cholecystitis. Five of the converted patients had an open subtotal cholecystectomy. In 23 patients LSC was performed for acute cholecystitis/empyema (four with Mirizzi type 1 syndrome) and six had severe fibrosis. In 15 patients the cystic duct and artery were clipped before division (*Fig. 1*). In 12 the gallbladder was incised at Hartmann's pouch (*Fig. 2*) and the cystic duct was sutured ($n = 2$) or ligated using an Endoloop ($n = 10$). In two patients the gallbladder bed was drained without isolating the cystic duct. CBD stones or stenoses were suspected before surgery on clinical, biochemical and ultrasonographic criteria in six of 29 patients. Four of the six underwent ERCP before surgery and in two of the four patients CBD stones were extracted. In the remaining two patients endoscopic retrograde cholangiography failed and both subsequently had negative intraoperative cholangiography. No other patient had intraoperative cholangiography. A suction drain was inserted in 14 cases.

Median operation time was 73 (range 45–130) min. There was one death; a 69-year-old woman died from a necropsy proven myocardial infarction 48 h after operation. Six patients had local complications: one had minor umbilical port sepsis, one patient had a self-limiting bile leak after simple drainage and four patients had subhepatic collections (two bile, two haematomas). Two of these required percutaneous ultrasonographically guided catheter drainage. All three bile leaks occurred in patients with acute cholecystitis in whom the cystic duct stump was secured with metal clips. Nine patients developed respiratory infections. Mean hospital stay was 5 (range 2–28) days. The extended hospital stay in one patient was due to prolonged catheter drainage from a liver abscess which was a complication of acute cholecystitis.

Discussion

Laparoscopic cholecystectomy is technically feasible in the majority of patients with acute cholecystitis but compared with elective operation the conversion rate to open surgery is higher and the operative time longer[7,8], with an increased risk of bile duct injury[9]. This series confirms the feasibility and safety of performing subtotal cholecystectomy laparoscopically thus avoiding the need for cholecystostomy or conversion to open operation in most patients. In some respects the laparoscopic approach may have certain advantages over the open technique. The operative view and approach to Calot's triangle is superior, allowing easier identification and isolation of the cystic duct–Hartmann's pouch junction which is the key to safe cholecystectomy. With the open technique this manoeuvre is more difficult and often requires the use of a purse-string closure technique from within the gallbladder, increasing the risk of bile leakage once the inflammatory process has resolved[1].

The hydrodissection technique using the blunt tip of the suction–irrigation apparatus was used when tissue was friable and inflamed to define and isolate the cystic duct, and to identify the anatomy at the cystic duct–Hartmann's pouch junction. However, the dissection may be more difficult when there is stone impaction in Hartmann's pouch and in cases of Mirizzi syndrome. In this situation removal of the stone by incising the site of stone impaction allows isolation of the cystic duct by continuing the incision into the posterior wall under direct vision in a circumferential fashion. Prograde dissection keeping close to the cystic duct or gallbladder wall allows secure placement of an Endoloop. This manoeuvre avoids leaving residual Hartmann's pouch while minimizing the risk of injury to the common or right hepatic duct. In cases where cystic duct isolation is impossible, placement of a drain will establish a controlled bile leak should this occur. Such bile leaks usually resolve spontaneously. If the leak persists, endoscopic sphincterotomy with or without temporary bile duct stenting is generally successful[10,11].

In this series the majority of operations were performed with the initial purpose of total removal of the gallbladder and were only converted to the subtotal technique when dense inflammation or fibrosis resulted in either inadvertent entry into the gallbladder, or when excessive bleeding occurred from the gallbladder bed. Great care was taken to remove all spilled stones with the use of a spoon forceps. An important aspect of the technique was to excise as much of the gallbladder as possible, leaving only a small residual strip of posterior wall. The liberal use of electrocoagulation with a hook dissector or scissors provided adequate haemostasis. Care must be taken to avoid excessive coagulation close to Calot's triangle. Leaving a strip of posterior gallbladder wall avoided inadvertent damage to the ducts of Lushka or superficial bile ducts in the gallbladder bed with resultant postoperative bile leak.

As with the open subtotal technique[2], the incidence of subhepatic collections afer LSC was low, considering that the majority of patients presented with acute cholecystitis; bile leaks from the cystic duct stump did not result in major complications. However, the use of a ligature is advised in the presence of acute cholecystitis to avoid the problem of dislodgement. We believe that preoperative ERCP should be mandatory in patients with severe cholecystitis in whom bile duct stones are suspected. In these cases extraction of CBD stones via the transcystic route is not usually feasible and laparoscopic exploration of the bile duct may be hazardous in the presence of severe inflammation

LSC is feasible in the majority of cases when total removal of the gallbladder is not possible in acute cholecystitis or when there is severe fibrosis. The procedure is safe, has an acceptably low morbidity rate, and reduces the need for either laparoscopic or percutaneous cholecystostomy or conversion to open cholecystectomy.

Background The roles of endoscopy and surgery in the management of *Ascaris lumbricoides* affecting the hepatobiliary and pancreatic system in adults were determined.

Methods All patients undergoing endoscopic retrograde pancreatography for ascariasis of the biliary or pancreatic system unresponsive to standard medical therapy were analysed. Worms were extracted using snare, Dormia basket or biopsy forceps. Success was defined as clearance of worms and eradication of symptoms.

Results Endoscopic extraction was performed in 25 patients with success in 19. Failures occurred in one patient with *Ascaris* in the gallbladder, and in five with associated strictures or stones. All six patients were treated successfully by surgery.

Conclusion Endoscopy was successful in the treatment of *Ascaris* infestation resistant to medical therapy in 19 of 25 patients. Surgery remains important in the management of infestations complicated by biliary or pancreatic strictures and stones, or worms in the gallbladder.

Ascaris infestation is often asymptomatic and most complications arise in children. At the Red Cross Children's hospital in Cape Town 20 per cent of acute paediatric admissions are directly due to *Ascaris* infestation and 70 per cent of children within the hospital were found to be carriers of *Ascaris*[1]. Surgical presentation usually results from massive infestation resulting in intestinal obstruction, volvulus or intussusception[2] with hepatobiliary and pancreatic *Ascaris* (HPA) being less common, accounting for only 10–19 per cent of *Ascaris*-related admissions[3,4].

Emergency admissions for HPA in adults are uncommon even in endemic areas and although worms appear to migrate frequently through the ampulla of Vater and into the common bile duct (CBD)[5] most appear to return spontaneously to the intestine[6,7]. Occasionally an ascarid (which may reach 15 cm in length) entering the CBD may cause a mechanical obstruction or result in spasm of the sphincter of Oddi resulting in obstruction. The main pancreatic duct (MPD) itself is rarely the site of *Ascaris* migration presumably because of its narrow calibre, and pancreatitis is usually secondary to invasion of the CBD causing obstruction of the ampulla of Vater and pancreatic duct[8]. The diagnosis is usually made by ultrasonographic identification of an ascarid within the CBD or MPD giving the typical 'bull's eye' appearance[9].

With increasing ease of travel and the movement of refugees, cases of hepatobiliary ascariasis are appearing in developed world countries[10–15]. Surgery has been regarded as the standard treatment when medical therapy has failed[4,16,17], and apart from short case reports[18,19] experience with endoscopic management is limited to a single series[20]. This paper reports the management of complicated HPA in adults unresponsive to standard medical therapy.

Paper accepted 16 December 1997

Patients and methods

From January 1986 to December 1995, 25 patients with hepatobiliary or pancreatic *Ascaris* infestations failed to respond to standard medical therapy. Mean age was 31 (range 14–80) years with a sex distribution of 22 women and three men. The majority of patients were from black townships (22 black, three white patients). Many patients were tertiary referrals having undergone failed medical treatment elsewhere. All patients were admitted to hospital and given symptomatic treatment which included cessation of oral intake, intravenous fluids, analgesia, anticholinergic antispasmodic agents (hyoscine butylbromide 20 mg four times daily), antihelmintics (mebendazole 100 mg twice daily) and antibiotics if cholangitis was present. Ultrasonography was performed on admission and endoscopic retrograde cholangiopancreatography (ERCP) was performed if symptoms failed to improve within the first week.

Worms were sometimes seen at endoscopy protruding through the ampulla of Vater (*Fig. 1*). When not directly visible they were

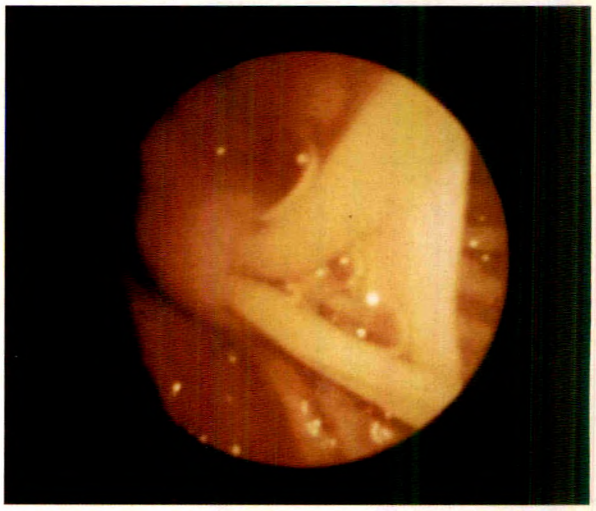

Fig. 1. Endoscopic view of ascarid emerging from the ampulla

demonstrated by ERCP after cannulation of the biliary or pancreatic ducts (*Fig. 2*). When worms were confirmed, extraction was attempted with a snare, Dormia basket or grasping forceps. Once engaged in the snare or forceps, worms were pulled out of the ampulla into the duodenum, and the duodenoscope subsequently withdrawn through the mouth with the worm. Care was required not to transect the worm by overtightening of the snare. When ERCP was unsuccessful surgery was performed. Patients were followed up clinically and with ultrasonography or ERCP to ensure successful worm eradication.

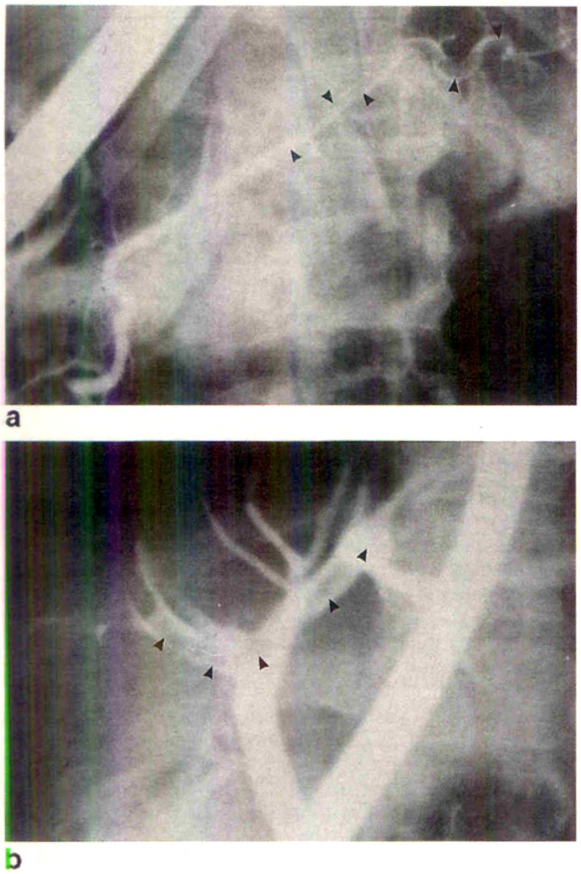

Fig. 2. Endoscopic retrograde pancreatography of ascarids (arrows) in **a** main pancreatic duct and **b** intrahepatic ducts

Results

Presentation

In this series HPA presented in four clinical forms: cholangitis ($n = 8$) (right hypochondrial pain, jaundice and high temperature); acute pancreatitis ($n = 8$) (epigastric pain and raised level of amylase); biliary colic ($n = 7$) (epigastric/right hypochondrial pain radiating to the back or shoulder); and painless obstructive jaundice ($n = 2$). Haematological and biochemical indices were non-specific with eosinophilia present in only five patients.

Endoscopic retrograde cholangiopancreatography findings and worm clearance

Worms were commonest in the extrahepatic (15 patients) and intrahepatic (nine patients) ducts and only rarely affected the pancreatic duct (three patients) or gallbladder (one patient). Calculi were present in six patients; in the CBD in three, the intrahepatic ducts in two and the pancreatic duct in one. Three patients had strictures. One extrahepatic biliary stricture was successfully dilated; one intrahepatic and one pancreatic duct required surgery.

Successful worm clearance was achieved in 19 patients with a median of one procedure; nine patients had more than one procedure with a maximum of five procedures. Endoscopic sphincterotomy was required in eight cases, seven biliary and one pancreatic. In five it was performed to remove stones co-existing with worms (including one pancreatic duct stone), in one because of a choledochoduodenal fistula and in two to facilitate removal of worms. Two complications may have been attributable to or exacerbated by ERCP: an empyema of the gallbladder in a patient on warfarin with myocardial ischaemia in whom multiple ERCPs were performed during removal of stones and ascarids; and a pancreatic pseudocyst in a patient with acute pancreatitis after attempts to remove a worm from the pancreatic duct.

Surgery

Worm extraction failed in six patients who underwent the surgical procedures listed in *Table 1*. There was no associated morbidity or mortality with these procedures.

Table 1 Operative management following failed extraction of *Ascaris lumbricoides* by endoscopic retrograde pancreatography

Patient	Age	Sex	No. of ERCPs	Indication	Operation
1	42	F	1	Trapped gallbladder ascarid	Laparoscopic cholecystectomy[29]
2	71	F	5	Empyema ? secondary to multiple ERCPs	Open cholecystectomy with exploration CBD
3	24	F	1	Persistence of three ascarids	Exploration of CBD with direct closure
4	70	M	3	Dead ascarids within CBD and left intrahepatic ducts and intrahepatic stones	Exploration of CBD with hepaticojejunostomy
5	26	F	2	Left hepatic duct stricture with intrahepatic ascarids	Exploration of CBD with hepaticojejunostomy access loop[30]
6	23	F	2	Main pancreatic duct stricture with proximal calculi and ascarid	Longitudinal pancreaticojejunostomy

ERCP, endoscopic retrograde cholangiopancreatography; CBD, common bile duct

Discussion

Ascaris lumbricoides is endemic where poverty, overcrowding, poor sanitation and an unsafe water supply exist, and involves around 155 million Africans[21]. Adult worms live in the proximal small bowel of humans and fertilized eggs, excreted in the faeces, may remain dormant for years. Following ingestion, the eggs hatch in the small intestine and penetrate the intestinal wall to enter the portal circulation or lymphatics. They migrate through the liver to the heart, through the pulmonary artery to the lungs where they burrow into the alveoli. Here they moult and migrate into the bronchi and trachea, and enter the oesophagus to return to the intestine again. After two further moultings they become mature adults.

Symptomatic *Ascaris* infestation is uncommon in adults. In this series 22 of 25 patients were women, predominantly young, black and with children. Ova are ingested from the soil and children are thus mostly at risk. Women may be more affected because of their greater contact with children in these communities where the carrier rate among children is around 70 per cent[22].

The majority of patients with pancreatic and biliary ascariasis respond to medical treatment of bowel rest, antispasmodic and antihelmintic drugs, and resolution of symptoms can be expected in 68–80 per cent[1,20]. Worms within the biliary tract are not killed by standard antihelmintic drugs. Pyrantel palmoate has no enterohepatic circulation[23], and mebendazole is poorly absorbed from the intestinal tract, with less than 1 per cent excreted in the bile[24]. Successful treatment appears to depend on worms returning to the small intestine where they are exposed to adequate concentrations of drugs. Failure of medical management may be due to the presence of dead worms, concomitant stones or strictures all of which prevent the worms returning to the duodenum. Since 1986 endoscopic treatment has become the treatment of choice in this unit, with surgery reserved for patients who fail to respond to an adequate trial of medical management or who show evidence of complications.

ERCP was successful in 19 of 25 patients who had not responded to adequate medical treatment. More than one procedure was required in nine patients. Failure was due to inability to reach ascarids in the gallbladder or intrahepatic ducts, or the presence of concomitant strictures preventing clearance of calculi and worms. Sphincterotomy was necessary in eight patients usually for the removal of calculi, and in only two patients was sphincterotomy performed solely for removal of the ascarid. Sphincterotomy should be avoided where possible as it appears to predispose to recurrent infestation by allowing easier access to the ampulla of Vater[25,26]. It is important to prevent reinfestation by administration of antihelmintic drugs although this is not always practicable within the poor social conditions which most of these patients have to endure.

Concomitant biliary stones were present in five patients. The association between *Ascaris* and intrahepatic stones has been noted in South-east Asia[5] and in South Africa[27], and *Ascaris* debris and ova are found in stones from these patients[16,28] supporting the hypothesis that *Ascaris* is one of the causes of intrahepatic stone disease in endemic areas.

Surgery continues to have a place in the management of HPA when endoscopic treatment has failed. Surgery was successful in all six cases and consisted of cholecystectomy in two patients[29], and removal of calculi and worms from the biliary ducts in three patients and pancreatic duct in one patient. Additional drainage procedures (hepaticojejunostomy or pancreaticojejunostomy) were performed in three patients. Recurrent stones have been successfully removed percutaneously via a hepaticojejunostomy access loop[30] on ten occasions in one patient in whom this was performed.

Despite its worldwide prevalence, *Ascaris* involving the pancreatic and biliary ducts is uncommon and usually responds to medical treatment. When this fails endoscopic removal is usually successful and surgery is now reserved for cases complicated by biliary or pancreatic strictures and stones, or worms in the gallbladder.

Anomalous pancreaticobiliary junction without congenital choledochal cyst

M. SUGIYAMA and Y. ATOMI

First Department of Surgery, Kyorin University School of Medicine, 6-20-2 Shinkawa, Mitaka, Tokyo 181, Japan
Correspondence to: Dr M. Sugiyama

Background Anomalous pancreaticobiliary junction (APBJ) without congenital choledochal cyst (CCC) carries a high risk of gallbladder carcinoma development. The aim of this study was to obtain information allowing early diagnosis and appropriate management.

Methods The clinical features, imaging findings and surgical outcome of 18 patients with APBJ without CCC were analysed retrospectively.

Results Fourteen patients had symptoms, including those of acute pancreatitis (five patients). In 16 patients the gallbladder showed abnormalities, including carcinoma (eight) and mucosal hyperplasia (11). Ultrasonography detected gallbladder carcinoma with 100 per cent sensitivity and mucosal hyperplasia with 91 per cent sensitivity. A long common channel was demonstrated by endoscopic retrograde cholangiopancreatography (ERCP) in all patients, endoscopic ultrasonography in nine of ten, and magnetic resonance cholangiopancreatography (MRCP) in five of five. Five of eight patients with gallbladder carcinoma underwent extended cholecystectomy with bile duct excision. Three patients with cancer and eight with no cancer had cholecystectomy alone. None developed bile duct carcinoma or acute pancreatitis after operation. All patients without malignancy remained asymptomatic for a mean follow-up period of 4·7 years.

Conclusion Prophylactic cholecystectomy is recommended for patients with APBJ without CCC. For early diagnosis of APBJ, gallbladder abnormalities on ultrasonography or acute pancreatitis of unknown aetiology should prompt further investigation with ERCP or less invasive imaging modalities such as endoscopic ultrasonography and MRCP.

Anomalous pancreaticobiliary junction (APBJ) is a rare congenital anomaly in which the pancreatic and biliary ducts unite outside the duodenal wall and form a long common channel of 15 mm or greater on endoscopic retrograde cholangiopancreatography (ERCP)[1,2]. APBJ is present in nearly all patients with congenital choledochal cyst (CCC)[2–4]. This anomaly is also found in patients without CCC[2–9]. APBJ without CCC is frequently associated with gallbladder carcinoma[2–9]. Therefore, early diagnosis and treatment of APBJ, before a malignancy arises, are essential[8]. APBJ with CCC is easily diagnosed, because typical symptoms (abdominal pain and mass, jaundice) or a dilated bile duct prompt examination with ERCP[10]. However, APBJ without CCC, particularly in the absence of gallbladder carcinoma, is difficult to diagnose because clinical features and imaging findings characteristic of APBJ without CCC have not been well documented. ERCP depicts APBJ most reliably[2], but is invasive and carries a potential for morbidity[11]. Accurate, less invasive, imaging techniques are desirable for diagnosing APBJ. A standard treatment for APBJ without CCC has not been established.

The aims of the present study were: (1) to analyse the clinical and imaging features of APBJ without CCC, to identify clues to early diagnosis; (2) to assess the diagnostic value of minimally invasive imaging modalities including endoscopic ultrasonography[12,13] and magnetic resonance cholangiopancreatography (MRCP)[14–16]; and (3) to analyse the long-term results of surgical treatment. The ultimate goal was to establish an optimal management strategy.

Patients and methods

Between February 1990 and December 1996, 18 adult patients with APBJ without CCC underwent surgical treatment at Kyorin University Hospital and two affiliated hospitals: five men and 13 women with a mean age of 45·9 (range 27–70) years. APBJ was defined as a common channel measuring 15 mm or longer at ERCP.

Before operation these patients underwent ultrasonography ($n = 18$), ERCP ($n = 18$), endoscopic ultrasonography ($n = 10$) and MRCP ($n = 5$). For endoscopic ultrasonography an echoendoscope equipped with a 7·5-MHz rotating transducer (GF-UM2/EU-M2 or GF-UM3/EU-M3; Olympus, Tokyo, Japan) was used. MRCP was performed using a 1·5-T clinical imager (Magnetom-vision; Siemens, Erlangen, Germany) with a phased-array coil. Magnetic resonance cholangiopancreatograms were obtained by using half-Fourier acquisition single-shot turbo spin-echo (HASTE) sequences[15,16].

Clinical presentation, laboratory, imaging and pathological findings, operative management and outcomes were analysed for the 18 patients. Follow-up extended from the date of operation to June 1997 or death (mean 3·3 years (range 7 months to 7 years)).

To provide the total numbers of patients with gallbladder carcinoma and with gallbladder mucosal hyperplasia, medical charts of inpatients at the three hospitals during the same period were reviewed. To determine the incidence of APBJ, ERCP reports were reviewed in the same way.

Results

Clinicopathological features

Of the 18 patients, 14 had symptoms, including abdominal pain (13 patients) and jaundice (2; bile duct invasion by gallbladder ($n = 1$) or pancreatic head ($n = 1$) carcinoma. Mean duration of symptoms before surgical treatment was

Paper accepted 9 December 1997

1·1 years (range 1 month to 6 years). Five patients experienced acute mild pancreatitis evidenced by acute onset of upper abdominal pain and threefold increase in serum amylase concentration.

Histological examination of the gallbladder ($n = 18$) revealed adenocarcinoma ($n = 8$; four with and four without mucosal hyperplasia), adenoma ($n = 1$), cholesterol polyp with hyperplasia ($n = 2$), mucosal hyperplasia ($n = 5$) or no abnormality ($n = 2$). All carcinomas were at an advanced stage with invasion to the subserosal layer or beyond. Mucosal hyperplasia was characterized by diffuse proliferation of ordinary gallbladder epithelium with a villous or spongiform pattern (*Fig. 1a*). The gallbladders with hyperplasia showed diffuse, 1·2–5·1 (mean 2·3) mm, mucosal thickening. Four patients (one with and three without gallbladder carcinoma) had cholelithiasis. Two patients without gallbladder lesions had pancreatic carcinoma. Mean age did not differ significantly between patients with gallbladder carcinoma (46·6 years) and those without pancreatobiliary malignancy (39·9 years) ($P = 0·14$, Wilcoxon test). The amylase level in gallbladder bile was raised (range 12 500–589 000 (mean 101 600) units/l) in 12 of 13 patients in whom bile was sampled.

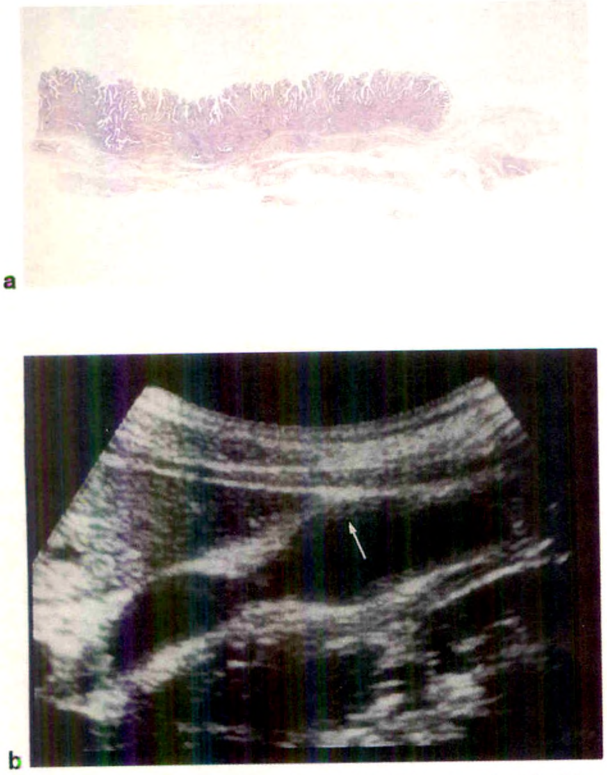

Fig. 1 Mucosal hyperplasia of the gallbladder associated with anomalous pancreaticobiliary junction without congenital choledochal cyst in a 38-year-old woman. **a** Pathological specimen (haematoxylin and eosin staining; original magnification × 4) shows marked villous hyperplasia of the gallbladder epithelium. **b** Ultrasonography shows a 3-mm symmetrical, diffuse, hypoechoic thickening of the inner layer (mucosal layer, arrow) of the gallbladder wall

Table 1 Detection of long common channel and gallbladder lesions by imaging

	Long common channel ($n = 18$)	Gallbladder carcinoma ($n = 8$)	Gallbladder mucosal hyperplasia ($n = 11$)
Ultrasonography	0 of 18	8 of 8	10 of 11

The arrowhead indicates the main pancreatic duct

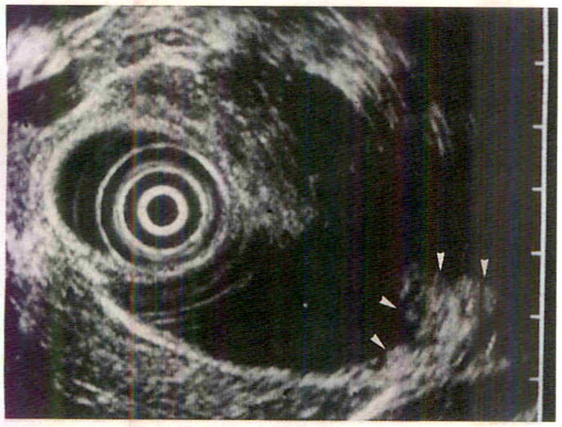

Fig. 4 Gallbladder carcinoma associated with anomalous pancreaticobiliary junction without congenital choledochal cyst in a 49-year-old man. Endoscopic ultrasonography shows a 34 × 20-mm hyperechoic sessile mass (arrowheads) in the gallbladder fundus. Histological examination of the surgical specimen revealed adenocarcinoma invading the subserosal layer of the gallbladder

common bile duct measured 5–14 (mean 9) mm. Endoscopic ultrasonography demonstrated a long common channel (12 mm or more) in nine of ten patients (*Fig. 2*) and a 5-mm channel in one. MRCP depicted a long common channel (12 mm or more) in all five patients examined with this modality (*Fig. 3b*). Ultrasonography failed to demonstrate a long common channel in any of the patients.

Ultrasonography and endoscopic ultrasonography detected and confirmed the diagnosis of all gallbladder carcinomas (*Table 1*). Carcinomas were demonstrated as a hyperechoic or hypoechoic sessile polyp (*Fig. 4*) or a large, irregularly surfaced, heterogeneously hypoechoic mass. In one patient with adenoma, ultrasonography and endoscopic ultrasonography demonstrated an 8-mm homogeneously hyperechoic, semipedunculated polyp but failed to distinguish it from carcinoma. Ultrasonography detected a cholesterol polyp in two patients but could not rule out carcinoma in one of the two. In this patient, however, endoscopic ultrasonography demonstrated aggregation of echogenic spots and accurately demonstrated the mass to be a cholesterol polyp. Mucosal hyperplasia was detected in ten of 11 patients by ultrasonography and in three of four by endoscopic ultrasonography. Ultrasonography and endoscopic ultrasonography showed a 1–5-mm symmetrical, diffuse, hypoechoic thickening of the inner mucosal layer of the gallbladder with an intact hyperechoic outer layer (*Fig. 1b*). Ultrasonography and endoscopic ultrasonography accurately detected the tumour in both patients with pancreatic carcinoma. MRCP failed to detect gallbladder lesions in all five patients examined with this modality.

The diagnosis of APBJ was established before operation in all 18 patients. In 14 symptomatic patients, polypoid lesions or mucosal thickening in the gallbladder, or pancreatic cancer, demonstrated by ultrasonography, led to further examination by ERCP, endoscopic ultrasonography or MRCP. APBJ was thereby diagnosed in all 14 patients. In four asymptomatic patients, gallbladder lesions that were detected incidentally by ultrasonography during regular checkups ($n = 3$) or pregnancy ($n = 1$) indicated a need for detailed examination. Subsequently, ERCP, endoscopic ultrasonography or MRCP confirmed APBJ.

Surgical treatment

All 18 patients were treated surgically. Of the eight patients with gallbladder carcinoma, five underwent extended cholecystectomy (excision of the gallbladder and its bed), excision of the extrahepatic bile duct, wide dissection of lymph nodes and Roux-en-Y hepaticojejunostomy. The other three patients received palliative cholecystectomy for well advanced carcinoma. Two patients with pancreatic carcinoma underwent pancreatic resection with cholecystectomy. Eight patients without malignant disease underwent cholecystectomy alone.

Of the eight patients with gallbladder carcinoma, only three are still alive 2·8–5 (mean 3·7) years after operation. Five patients died from carcinoma 3–30 (mean 14) months after operation. Both patients with pancreatic carcinoma died from recurrent disease, 8 months and 2 years after operation. All eight patients without malignancy have been alive and asymptomatic for a mean of 4·7 years (range 7 months to 7 years) since cholecystectomy. None of the 18 patients developed acute pancreatitis or bile duct carcinoma. One patient with bile duct excision experienced acute cholangitis which was managed conservatively.

Incidence of anomalous pancreaticobiliary junction and total number of gallbladder lesions

The review of ERCP records in 934 cases during the same period yielded 47 cases (5·0 per cent) of APBJ (29 with and 18 without CCC). All 47 patients underwent surgical treatment. Of the 29 patients with APBJ and CCC, four had gallbladder carcinoma, two had bile duct carcinoma and 13 had mucosal hyperplasia of the gallbladder. As well as 12 patients with gallbladder carcinoma and APBJ (four with and eight without CCC), 57 other patients without APBJ (mean age 57·1 years) were treated for gallbladder carcinoma during the same period. Of 625 patients without APBJ who underwent cholecystectomy, two (0·3 per cent) had severe mucosal hyperplasia of the gallbladder at histological examination.

Discussion

APBJ without CCC was found in 1·9 per cent of cases detected by ERCP in the present study. APBJ without CCC was associated with a high prevalence of gallbladder carcinoma (eight of 18 patients), which is consistent with the results of previous studies (33–73 per cent)[2,6,8,9]. Gallbladder carcinoma in patients with APBJ without CCC ($n = 8$) constituted 12 per cent of all patients with gallbladder cancer ($n = 69$) treated during the same period. The mean age of patients with gallbladder cancer and APBJ was lower, by approximately 10 years, than that of those without APBJ, as reported previously[2,8].

Gallbladders with mucosal hyperplasia showed a marked (1·2–5·1 mm), diffuse thickening of the mucosa, compared with the mucosal height (less than 0·6 mm)[17] of the normal gallbladder. The prevalence of mucosal hyperplasia was high (11 of 18 patients) in the present series, as in previously reported series of APBJ (39–64 per cent)[17,18]. In patients without APBJ, severe mucosal hyperplasia is observed only rarely: in 0·3 per cent (in the present study), 0·4 per cent[19] or 0·7 per cent[20]. Therefore, mucosal hyperplasia strongly suggests the presence of APBJ.

The aetiology of gallbladder carcinoma in APBJ without CCC has not been fully clarified. In patients with APBJ, gallstones do not appear to contribute to carcinogenesis, based on the low rate of gallstone detection (13–18 per cent in previously reported series[2,8]; one of eight patients in the present study), in contrast to patients without APBJ. APBJ allows reflux of pancreatic juice into the biliary tract, as reflected by the high amylase level in gallbladder bile in the present and previous studies[7]. Refluxed proteolytic pancreatic enzymes and phospholipase A_2 are activated in the biliary tract[21]. Phospholipase A_2, which has a direct proliferative effect on the gallbladder mucosa[18], produces lysophosphatidylcholine, which has a cytotoxic effect[21]. These agents may cause mucosal hyperplasia and carcinoma of the gallbladder. A sequence of hyperplasia, characterized by increased cellular kinetics, through dysplasia to carcinoma may be involved in the carcinogenesis that occurs in APBJ without CCC[17,18,22]. In the present study, 16 of 18 patients had mucosal hyperplasia, adenoma or carcinoma of the gallbladder. The present series included two pancreatic carcinomas. Only a few pancreatic cancer cases with APBJ have been reported[23]. The relationship between these two diseases thus remains unclear.

In the present study, five of the 18 patients developed acute pancreatitis. The incidence is reportedly 44–68 per cent in APBJ[4,6,24]. Although the hydropressure within the pancreatic duct is usually greater than in the bile duct[25], bile may reflux into the pancreatic duct via the anomalous junction in some situations, such as postprandial gallbladder emptying. This reflux may contribute to acute pancreatitis. All three patients with a history of previous episodes of acute pancreatitis had no further attacks after cholecystectomy alone.

In the present study, endoscopic ultrasonography (90 per cent) and MRCP (100 per cent) were almost as sensitive as ERCP (100 per cent) in the detection of APBJ although only five patients had MRCP. Both imaging techniques are less invasive than ERCP. Furthermore, endoscopic ultrasonography allows accurate differentiation of polypoid lesions in the gallbladder (carcinoma *versus* cholesterol polyps)[12,13], which facilitated the planning of operative procedures. MRCP failed to depict gallbladder lesions. However, MRCP is neither operator-dependent nor associated with any discomfort for patients, in contrast to ERCP and endoscopic ultrasonography. Therefore, endoscopic ultrasonography and MRCP are potentially useful alternatives to ERCP for diagnosing APBJ[13,26].

Clues to the diagnosis of APBJ without CCC have not been described. Of the present 18 patients, 14 had symptoms. Screening with ultrasonography detected pancreatobiliary abnormalities in all patients. With the exception of the two patients with pancreatic carcinoma, all gallbladders showed diffuse mucosal hypoechoic thickening (hyperplasia) and/or polypoid lesions (carcinoma or adenoma) on ultrasonography. Polypoid lesions suggest adenoma or carcinoma, if ultrasonography does not show characteristic features of cholesterol polyps (usually less than 10 mm in diameter, pedunculated, and with a single tiny echogenic spot or an aggregation of echogenic spots) or adenomyomatosis (multiple intramural cysts)[12]. Suspected adenomas or carcinomas require further examination with endoscopic ultrasonography or ERCP for differentiation and staging, and to ascertain the presence of APBJ[12,13]. Accordingly, polypoid gallbladder lesions or diffuse hypoechoic thickening of the gallbladder mucosa demonstrated on ultrasonography, or acute pancreatitis of unknown aetiology, should prompt further investigation to screen for APBJ.

The treatment of choice for APBJ with CCC is excision of the extrahepatic bile duct and gallbladder with Roux-en-Y reconstruction of the biliary tree[3]. However, a standard treatment protocol for APBJ without CCC has not been established. Gallbladder carcinoma associated with APBJ should be treated utilizing the procedure for gallbladder carcinoma without APBJ. These carcinomas require cholecystectomy, resection of the liver (gallbladder bed resection or major hepatectomy), extrahepatic bile duct excision and wide dissection of lymph nodes, based on the tumour stage[27].

For patients with APBJ without CCC but with no cancer, the authors recommend prophylactic cholecystectomy because of the high possibility of gallbladder carcinoma developing in the future. However, excision of the extrahepatic bile duct is unnecessary because bile duct carcinomas rarely develop in patients with APBJ without CCC[5]. In the present study, no bile duct carcinomas developed after cholecystectomy not involving resection of the APBJ. No patient experienced either acute pancreatitis or acute cholangitis after operation. On the other hand, Lilly *et al.*[28] advocated excision of the extrahepatic bile duct, particularly for symptomatic patients. However, they reported a high (50 per cent) incidence of postoperative recurrent cholangitis. Reconstruction of the non-dilated biliary tree carries a risk of postoperative stricture and recurrent cholangitis. Nevertheless, meticulous pathological examination of the gallbladder and careful follow-up are necessary for patients treated with cholecystectomy alone.

In conclusion, APBJ without CCC is a high-risk condition for the development of gallbladder carcinoma. Prophylactic cholecystectomy before carcinoma develops is recommended. For early diagnosis of APBJ, gallbladder abnormalities on ultrasonography (polypoid lesions or diffuse hypoechoic thickening of the mucosal layer), or acute pancreatitis of unknown aetiology, should prompt further investigation with ERCP or less invasive imaging modalities, such as endoscopic ultrasonography and MRCP.

Follow-up of more than 10 years after endoscopic sphincterotomy for choledocholithiasis in young patients

M. SUGIYAMA and Y. ATOMI

First Department of Surgery, Kyorin University School of Medicine, 6-20-2 Shinkawa, Mitaka, Tokyo 181, Japan

Background With the advent of laparoscopic cholecystectomy, the indications for endoscopic sphincterotomy (ES) have been extended to young patients with choledocholithiasis. However, the long-term results of ES are largely unknown.

Methods Between 1977 and 1986, 115 patients aged 60 years or less underwent ES for choledocholithiasis. Stone classification, and early and long-term outcomes of ES were analysed retrospectively.

Results Early complications occurred in nine patients (7·8 per cent), but there were no deaths. ES and stone clearance were successful in 110 patients. Long-term information was available in 103 of the 110 patients, with a mean overall follow-up duration of 14·2 (range 10·4–19·3) years. Ten patients (9·7 per cent) developed late complications, including stone recurrence and/or cholangitis (nine patients) and acute cholecystitis (one of 23 patients with the gallbladder *in situ*). The choledochal complication rate was somewhat higher in patients with calcium bilirubinate stones at ES (seven of 65 patients) than in those with cholesterol stones (two of 38 patients). Choledochal complications were manageable endoscopically.

Conclusion Approximately 10 per cent of patients develop late complications. However, endoscopic retreatment is safe and effective. ES is a reasonable method for treating choledocholithiasis, even in young patients.

Young patients do not develop common bile duct stones as often as elderly patients. However, the treatment strategy selected for choledocholithiasis in young patients is an important issue to be resolved in the era of laparoscopic cholecystectomy[1]. Treatment options include endoscopic sphincterotomy (ES), laparoscopic surgery (transcystic stone retrieval or direct choledochotomy) and open bile duct exploration[1]. ES is a widely accepted method of extracting common bile duct stones in elderly or high-risk patients and in those with severe cholangitis or pancreatitis[2–4]. ES is associated with potential long-term complications, such as biliary pain, stone recurrence and cholangitis, secondary to sphincter ablation or papillary stenosis. However, the risks of developing such late complications are negligible in elderly, and even many high-risk, patients because of their relatively short life expectancies. Recently, the indications for ES have been extended to young patients with few, if any, non-biliary disorders, in association with the advent of laparoscopic cholecystectomy[5–7]. Combined use of laparoscopic cholecystectomy and preoperative or postoperative ES is a minimally invasive and relatively convenient treatment for co-existing gallbladder and ductal stones. However, this emerging indication of ES is still controversial because little information is available on the long-term (10 years or more) outcome of ES[8,9], particularly in young patients.

To evaluate the role of ES for choledocholithiasis in young patients, the present retrospective study analysed clinical features of young patients (aged 60 years or less) who underwent ES for choledocholithiasis, as well as the short-term and long-term (10 years or more) results of ES. Furthermore, the relation of stone classification and long-term outcome was analysed.

Patients and methods

Between 1977 and 1986, a total of 382 patients underwent ES for choledocholithiasis at this hospital and two affiliated hospitals. Patients with concomitant hepatolithiasis or bile duct stricture were excluded from the study. Among these patients, 115 (30·1 per cent) were 60 years or younger at the time of the initial endoscopic procedure. There were 54 men and 61 women with a mean age of 50 (range 21–60) years.

ES was usually performed to the upper margin of the papillary roof, using side-view duodenoscopes and standard pull-sphincterotomes. Stone extraction with a basket or balloon catheter was attempted routinely during the initial endoscopic procedure.

Clinical features, stone classifications, and early and long-term outcomes of ES were analysed in these young patients. Gallstones were classified as cholesterol, calcium bilirubinate or black stones, according to the cross-sectional findings[10]. Cholesterol stones showed a radial pattern with a white to light yellow colour. Calcium bilirubinate stones (brown pigment stones) had multiple concentric layers with a brown colour. These stones are common in Japanese patients, particularly those with primary common bile duct stones. Black stones were dark brown or black, friable and amorphous. These stones contain mainly unconjugated bilirubin and are called pigment stones in the USA and Europe. Early complications (within 30 days of ES) were classified according to the 1991 consensus guidelines[11].

Long-term follow-up data were obtained from medical charts at the authors' outpatient clinic or from the patients, their families and/or their local practitioners by mail and/or telephone, in March 1997. Accordingly, the minimum overall duration of follow-up was 10 years. The data included (1) biliary symptoms (abdominal pain, jaundice, fever and chills), (2) medical investigation (liver function tests and imaging studies) if performed, (3) medical and surgical treatment, and (4) causes of death, since the first ES. If symptoms, liver function tests or abdominal ultrasonography indicated possible biliary pathology, patients were advised to undergo repeat endoscopic retrograde cholangiopancreatography (ERCP).

Paper accepted 16 December 1997

Results were analysed by means of Fisher's exact probability test. Differences were considered significant at a P value of less than 0·05. The probability of biliary complications occurring during follow-up was determined using the Kaplan–Meier method.

Results

Among the 115 young patients who underwent ES for choledocholithiasis, 66 had previously undergone cholecystectomy, with ($n = 40$) or without ($n = 26$) bile duct exploration. The interval between primary surgery and ES ranged from 6 days to 11 years (mean 15 months). Eight patients underwent ES within 30 days of cholecystectomy without bile duct exploration. Six patients had undergone two operations for bile duct stones. At ES, 49 patients had *in situ* gallbladders; 36 had gallbladder stones and 13 did not. Of the 115 patients, 36 presented with acute cholangitis and 15 with gallstone pancreatitis. Thirteen patients had concomitant medical problems, including liver cirrhosis ($n = 5$), recent myocardial infarction ($n = 2$), chronic renal failure ($n = 2$), diabetes ($n = 2$), chronic obstructive pulmonary disease ($n = 1$) and congestive heart failure ($n = 1$). ES was performed on an emergency basis in 40 patients with acute cholangitis ($n = 27$) or acute pancreatitis ($n = 13$).

ES was successful in 112 (97·4 per cent) of 115 patients but failed in three patients with gallbladder and bile duct stones. At ERCP, the intrahepatic bile ducts showed no abnormalities. Stenosis of the extrahepatic bile duct or papillary orifice was not found. Bile duct clearance was achieved in 110 patients (95·7 per cent), after one endoscopic procedure in 91 patients and after two or more procedures in 19. The remaining two patients with previous choledochal exploration underwent surgical treatment for retained bile duct stones.

Early complications (within 30 days of ES) occurred in nine patients (7·8 per cent), and included bleeding and acute pancreatitis (*Table 1*). One perforation necessitated emergency surgery. The eight remaining complications were mild and all were managed medically. No ES-related deaths occurred. Only one of the 13 patients with concurrent medical problems experienced an ES-related complication (mild acute pancreatitis).

Table 1 Early complications after endoscopic sphincterotomy in 115 patients

	No. of patients	Required operation
Acute pancreatitis	4 (3·5)	0
Haemorrhage	3 (2·6)	0
Perforation	1 (0·9)	1
Acute cholangitis	1 (0·9)	0
Total	9 (7·8)	1

Values in parentheses are percentages

Of 33 patients with gallbladder stones at the time of ES, 23 underwent elective cholecystectomy 5–37 (mean 10) days after successful ES. The gallbladder was left *in situ* after ES in 23 patients with ($n = 10$) or without ($n = 13$) cholelithiasis.

Patients with previous cholecystectomy had a high prevalence of calcium bilirubinate stones in calculi extracted at ES (*Table 2*). However, all eight patients with recent (30 days or less) cholecystectomy had cholesterol stones, which were considered to be residual at the time of surgery. Among those with gallbladder *in situ*, most patients with gallbladder stones had cholesterol stones but all patients without gallbladder stones had calcium bilirubinate stones. None of the present patients had black stones.

Long-term outcome

Long-term information was available in 103 (93·6 per cent) of 110 patients with successful ES and bile duct clearance. The overall duration of follow-up ranged from 10·4 to 19·3 (mean 14·2) years. Seven patients (6·4 per cent) were lost to follow-up. During the follow-up period, 16 patients died from non-biliary disease 6·5–17·3 (mean 12·0) years after ES. There were no deaths related to biliary disease.

Of the 103 patients, ten (9·7 per cent) experienced biliary symptoms during follow-up (*Table 3*). Five patients developed acute cholangitis 1·7–11·0 (mean 5·3) years after ES. In these five patients, repeat ERCP revealed recurrent bile duct stones with papillary stenosis in three,

CBD, common bile duct

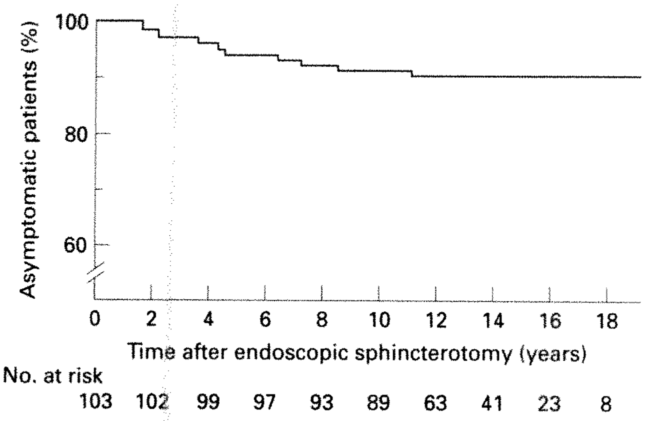

Fig. 1 Kaplan–Meier plot for the absence of late complications in 103 patients who underwent successful endoscopic sphincterotomy, achieving ductal clearance

bile duct stones alone in one and papillary stenosis alone in one. Another four patients presented with obstructive jaundice and/or biliary pain 2·3–7·3 (mean 5·2) years after ES. ERCP showed recurrent choledocholithiasis with ($n = 3$) or without ($n = 1$) papillary stenosis. In the seven patients with papillary stenosis, the initial ES had been performed to the upper margin of the papillary roof (a large incision; $n = 5$) or to below the upper margin (a middle incision; $n = 2$). Only one of the seven patients had experienced an early complication (mild pancreatitis) after ES. Of the 23 patients with the gallbladder *in situ*, one with gallbladder stones developed acute cholecystitis 2·3 years after ES, which necessitated cholecystectomy. In this patient, repeat ERCP detected no abnormalities in the common bile duct. No cases of liver abscess or biliary malignancy were recorded after ES.

The eight patients with recurrent choledocholithiasis underwent successful transpapillary stone extraction, combined with repeat ES in six. All eight had calcium bilirubinate stones at recurrence. One patient with acute cholangitis without bile duct stones underwent ES. Neither early nor long-term complications occurred after endoscopic retreatment in these nine patients.

Ninety-three patients were free from biliary symptoms as of March 1997 or until death. During follow-up, 19 patients underwent repeat ERCP, mostly because of mild cholestatic liver dysfunction or suspected bile duct stones on ultrasonography; seven of the 19 patients underwent ERCP in 1997. However, none of these patients had evidence of recurrent choledocholithiasis or papillary stenosis on ERCP.

Excluding one case of acute cholecystitis, biliary complications occurred in two of 38 patients with cholesterol stones and in seven (11 per cent) of 65 with calcium bilirubinate stones at the initial ES; the difference was not significant ($P = 0·28$) (*Table 3*). The cumulative incidence of late complications was 9 per cent at 10 years and 10 per cent at 15 years (*Fig. 1*). Most complications occurred during the first 10 years.

Discussion

In the present study, young patients underwent ES mainly for recurrent bile duct stones after cholecystectomy or for acute complications of choledocholithiasis, including acute cholangitis and acute pancreatitis. The majority of young patients had no surgical risks due to concurrent medical problems, in contrast to elderly patients. However, 4·3 per cent of the present patients had liver cirrhosis. Surgical treatment of choledocholithiasis in such patients has been reported to carry an extremely high risk[12]. In the present series, patients with cirrhosis underwent ES successfully and safely.

In the present study, the success rate was 97·4 per cent for ES and 95·7 per cent for stone extraction. The early complication rate after ES was 7·8 per cent with no deaths. Most of the complications were mild and could be managed medically, the exception being one case of a perforation which occurred early in the authors' experience. A previous study collected a large amount of data on early complications of ES[11]. Overall morbidity and mortality rates were reported to be 7–11 per cent and 0–2 per cent respectively[11]. The ES complication rate depends on technical factors rather than concurrent medical risk factors[2,13]. Accordingly, ES carries a risk for early complications even in young patients. The results of the present study were, however, acceptable in young, otherwise healthy patients.

In the present study, a relatively small number of patients (6·4 per cent) was lost to follow-up. All patients with biliary symptoms underwent repeat ERCP. Furthermore, most asymptomatic patients with mild cholestatic liver dysfunction or suspected bile duct stones on ultrasonography underwent ERCP. Therefore, the true late complication rate after ES could be calculated. The incidence of biliary complications during the mean follow-up period of 14·2 years was 9·7 per cent. Almost all complications occurred within 10 years of ES. Most of the late complications were recurrent bile duct stones and acute cholangitis, the incidence being 8·7 per cent. No biliary malignancies developed after ES. In the literature late biliary complications after ES have occurred in 5·8–18 per cent of patients during a mean follow-up of less than 8 years (*Table 4*). However, only a few reports have described the late complication rate (5·8 per cent[9] and 24 per cent[8]) for a mean follow-up exceeding 10 years. The present figure (9·7 per cent) takes an intermediate position between the two previously reported results. The present data compare favourably with the results obtained by surgical duct re-exploration for recurrent stones (a complication rate of 18–33 per cent after 5–10 years of follow-up[21,22]). However, the literature concerning long-term outcomes after primary surgery for bile duct stones, particularly cholesterol stones (secondary stones), is scarce. Furthermore, long-term results after laparoscopic surgery for choledocholithiasis have not been reported.

In the present series, seven of nine late choledochal complications were associated with papillary stenosis. An inadequate incision and a bleeding sphincterotomy requiring a sclerosing injection have been reported to be potential risk factors for papillary stenosis[9,19]. However, the present study could not confirm the theory. All recurrent stones were calcium bilirubinate stones, which are generally considered to result from bacterial infection[10,23]. Bactobilia, bile stasis and papillary stenosis may play important roles in the pathogenesis of recurrent stones[24,25]. Calcium bilirubinate stones are often found in cases of primary bile duct stones or recurrent stones[10]. Such patients require careful follow-up after ES. Late complications were managed safely and successfully with ERCP.

Table 4 Summary of published data concerning follow-up after endoscopic sphincterotomy for choledocholithiasis

Reference	Year	No. of patients with follow-up	Mean (range) follow-up (years)	Late complications (%)

Acute cholecystitis developed after ES in one of ten patients with gallbladder calculi but in none of 13 patients with an acalculous gallbladder. ES had previously been considered to increase the risk of acute cholecystitis. However, recent reports have demonstrated a low incidence of cholecystitis after ES, particularly in patients with an acalculous gallbladder[26,27]. The authors have shown that ES actually improves gallbladder motility somewhat[27]. Prophylactic cholecystectomy for an acalculous gallbladder may be unnecessary even for young, essentially healthy, patients.

In treating common bile duct stones, ES is basically safe but does carry a risk of early complications. Even in young patients, ES should be performed by skilful endoscopists. Approximately 10 per cent of patients develop late complications such as stone recurrence or acute cholangitis, mostly within 10 years of ES. Careful follow-up after ES is necessary, particularly for patients with calcium bilirubinate stones at ES. Although the late complication rate after ES is not negligible, retreatment with ERCP is safe and effective. ES is a reasonable method for treating choledocholithiasis, even in young patients.

---

Background Recent reports suggest a better postoperative weight gain after pylorus-preserving pancreatoduodenectomy (PPPD) compared with standard pancreatoduodenectomy (PD). Factors that could also influence postoperative weight gain, such as tumour-positive resection margins and tumour recurrence, have not been taken into account in these studies. The aim of this prospective study was to evaluate weight gain in the first 15 months after PD or PPPD and to investigate the influence of other tumour-related factors.

Methods From 1991 to 1995, 140 patients underwent subtotal pancreatoduodenectomy; 125 patients underwent resection for malignant disease of the pancreatic head region (56 had PD and 69 PPPD). Patients' weights were evaluated in the pre-illness phase, before operation and during four postoperative phases (at 3, 7, 11 and 15 months). Weight was calculated as a percentage of the pre-illness weight. Patients were subdivided according to tumour status: PD with positive and PD with negative tumour status; PPPD with positive and PPPD with negative tumour status. Tumour-positive status was defined as either microscopically tumour-positive resection margins or radiologically or cytologically proven tumour recurrence within 2 years of surgery.

Results Five patients died during the hospital stay (PD, four; PPPD, one) (overall mortality rate 4 per cent). There was no difference in overall weight gain between patients having PD and PPPD. There was, however, a difference in patients with positive and negative tumour status for PD ($P = 0.0003$) and PPPD ($P < 0.0001$).

Conclusion There is only a minimal difference in postoperative weight gain between patients having PD and PPPD. Differences in postoperative weight gain are related more to positive resection margins and tumour recurrence than to the type of resection.

Pancreatoduodenectomy is a major surgical procedure which is accompanied by a mortality rate of less than 5 per cent in specialized centres[1–6]. This procedure still has a significant morbidity rate of up to 60 per cent[2,3,5–8]. After the introduction of pylorus-preserving pancreatoduodenectomy (PPPD), early studies suggested that postoperative gastric emptying was delayed[9–12]. This has not been confirmed in recent reports[13–15] and the PPPD is thought to have advantages over the standard Whipple procedure. The procedure is less time consuming and has been reported to be associated with less intraoperative blood loss[13,14,16]. PPPD is now accepted in most centres as the favoured reconstruction after pancreatic head resection.

Another important advantage of PPPD is better postoperative weight gain compared with that following standard Whipple resection, as reported in a number of retrospective studies[13,14,17]. In these studies postoperative weight gain was usually assessed only at one time point in the postoperative period. After pylorus-preserving resection more patients were reported to gain weight in the postoperative period than following standard Whipple resection, but the exact time point of postoperative weight assessment and the number of weight measurements were not stated[14]. Zerbi *et al.*[13] assessed weight gain as a percentage of pre-illness weight and demonstrated an advantage for patients after pylorus-preserving resection at 6 months after operation[13]. It is, however, remarkable that tumour recurrence after resection was not taken into account in these studies. Tumour recurrence is probably an important factor in determining weight gain.

From 1993, the preferred surgical reconstruction in the authors' department changed gradually from the standard Whipple procedure towards the pylorus-preserving resection. In this study a consecutive series of patients undergoing pancreatoduodenectomy for malignant disease of the pancreatic head region was evaluated prospectively to determine whether the pylorus-preserving procedure resulted in improved weight gain in the first postoperative year compared with the standard Whipple resection. The influence of microscopically tumour-positive resection margins and tumour recurrence on weight gain was taken into account in the analysis.

Patients and methods

From 1991 to 1995, 140 consecutive patients underwent subtotal pancreatoduodenectomy. Fifteen patients had benign disease on

Presented in part to a meeting of the American Gastroenterological Association in Washington, DC, USA, May 1997, and published in abstract form as *Gastroenterology* 1997; **112**: 489
Paper accepted 9 December 1997

histopathological examination of the resection specimen and were therefore excluded from the study, leaving 125 patients who underwent resection for malignant disease of the pancreatic head region. Fifty-six patients were treated with a standard Whipple resection and 69 underwent PPPD. Before January 1993 only standard Whipple's resections were performed. In the following period a gradual preference for the pylorus-preserving procedure developed. Other changes in the surgical protocol that were introduced in 1993 were: reconstruction with one jejunal loop for the pancreatic, biliary and gastric anastomosis instead of a separate Roux-en-Y loop for the pancreatic and biliary anastomosis; the pancreaticojejunal anastomosis was performed in one running layer instead of two layers. Furthermore, transluminal drainage of the pancreatic duct was performed only in the earlier period, before 1993.

All data concerning preoperative evaluation, intraoperative parameters, and postoperative morbidity and mortality were collected prospectively. Both groups were compared with respect to age, sex, preoperative bilirubin (μmol/l) and albumin (g/l) levels, operating time, blood loss and transfusions, histopathological diagnosis, microscopic radicality of the resection, postoperative morbidity and mortality. Morbidity was defined as any postoperative complication requiring medical or surgical intervention, causing prolonged hospital stay, readmission to the intensive care unit or leading to postoperative death. Mortality was defined as death during hospital stay.

Pancreatic endocrine and exocrine function were compared in these two groups. Pancreatic endocrine insufficiency was defined as glucose intolerance necessitating oral medication or insulin administration. Pancreatic exocrine insufficiency was defined as fat intolerance, requiring pancreatic exocrine supplementation during outpatient treatment, which improved with pancreatic enzyme treatment. Patients receiving postoperative radiotherapy and chemotherapy were identified in both groups. (A number of patients received additional radiotherapy or chemotherapy in a randomized multicentre trial (European Organisation for Research on Treatment of Cancer)).

Weight assessment

Preoperative and postoperative weights were computed as a percentage of the pre-illness weight, as inquired at the preoperative assessment. Postoperative weights were measured prospectively in the outpatient clinic and divided into four successive postoperative phases: 3 ± 1, 7 ± 1, 11 ± 1 and 15 ± 1 months after operation.

Positive tumour status

Patients were divided into those with positive and negative tumour status. Patients with positive tumour status were defined as having microscopically non-radical resection margins or postoperative tumour recurrence during the first 2 years of follow-up. Tumour recurrence was defined as radiologically or cytologically proven tumour recurrence within 2 years after surgery. A microscopically radical resection was defined as both tumour-free resection margins and dissection margins of the resection specimen on histopathological examination. All patients had macroscopically radical resections, as this is a major requirement for performing pancreatoduodenectomy at this centre.

Thus, there were four groups: patients who had undergone a standard Whipple procedure with negative tumour status, patients who had a standard Whipple procedure with positive tumour status, patients who had a pylorus-preserving resection with positive tumour status and those who had PPPD with negative tumour status.

Statistical analysis

Weight was calculated as the mean(s.e.m.) percentage of pre-illness weight. Statistical analysis was performed with χ^2 analysis, the two-tailed Fisher's exact test and the Mann–Whitney *U* test, as applicable. $P < 0{\cdot}05$ was considered statistically significant.

Results

Eighty-two per cent of the standard Whipple resections were performed before July 1993, whereas 90 per cent of the pylorus-preserving resections were performed after July 1993. There were no differences in patients' characteristics, preoperative weight loss, plasma bilirubin and albumin levels (*Table 1*). Duration of the standard Whipple resection was significantly longer than that of PPPD: 6·4 *versus* 4·8 h. Blood loss and transfusion need were higher in patients who had a standard Whipple resection. There were no differences in histopathological diagnosis, microscopic radicality of the resection or postoperative morbidity. The overall morbidity rate for standard Whipple's resection and PPPD was 50 and 42 per cent respectively. The overall mortality rate was 4 per cent with no difference between the two groups.

Follow-up data were available for 49 of 56 patients after standard Whipple's resection (postoperative death, four; lost to follow-up, three). Sixty-six of 69 patients could be analysed after PPPD (postoperative death, one; lost to follow-up, two). Tumour recurrence was detected

Table 1 Period of resection, patient characteristics, intraoperative factors, pathology, and postoperative morbidity and mortality for 125 patients who underwent operation from January 1991 to November 1995 for malignant disease of the pancreatic head area

	PD ($n = 56$)	PPPD ($n = 69$)

Values in parentheses are percentages unless otherwise stated. PD, standard Whipple resection; PPPD, pylorus-preserving pancreatoduodenectomy; PRBCs, packed red blood cells. *$P < 0{\cdot}0001$ *versus* PD (χ^2 analysis); †$P < 0{\cdot}0001$, ‡$P = 0{\cdot}02$ *versus* PD (Mann–Whitney *U* test) during the study period in 28 patients after standard Whipple resection and in 31 after PPPD (57 *versus* 47 per cent respectively, $P = 0\cdot28$). Furthermore, six patients with a non-radical Whipple resection did not show signs of tumour recurrence and therefore 34 were classified as having a positive tumour status after standard Whipple resection. Six patients showed no signs of tumour recurrence after a non-radical pylorus-preserving resection, and therefore 37 patients in this group were classified as having a positive tumour status. Similar numbers of patients had complete follow-up in both groups. Median follow-up (including patients who died during follow-up) was 17 and 18 months for standard and pylorus-preserving resection respectively ($P = 0\cdot20$). The number of patients receiving postoperative radiotherapy or chemotherapy was no different for each procedure (*Table 2*).

Patients had a higher incidence of clinical pancreatic exocrine insufficiency after standard Whipple resection compared with PPPD: 73 and 56 per cent respectively. This, however, was not statistically significant ($P = 0\cdot06$). There was no difference in the incidence of pancreatic endocrine insufficiency between the two groups (*Table 3*).

Postoperative weight

Preoperative weight and weight 3 months after operation was no different between the standard Whipple resection and the pylorus-preserving resection. Weight at 7, 11 and 15 months after operation was not significantly different between the two surgical procedures (*Fig. 1*).

Patients with negative tumour status ($n = 44$) had a postoperative weight gain from a mean(s.e.m.) of 87(1·3) per cent at 3 months to 94(1·7) per cent of pre-illness weight at 15 months after operation. Patients with positive tumour status ($n = 71$) had an overall weight loss from 86(1·0) to 81(2·2) per cent of pre-illness weight in the same period (*Fig. 2*).

There were no differences in mean weight among the four subgroups on admission and at 3 months after operation. There was no difference in weight gain between the two procedures, in patients with negative tumour status or in those with positive tumour status within 15 months of operation (*Fig. 3*).

Total weight gain from 3 to 15 months after operation was no different between the standard Whipple procedure

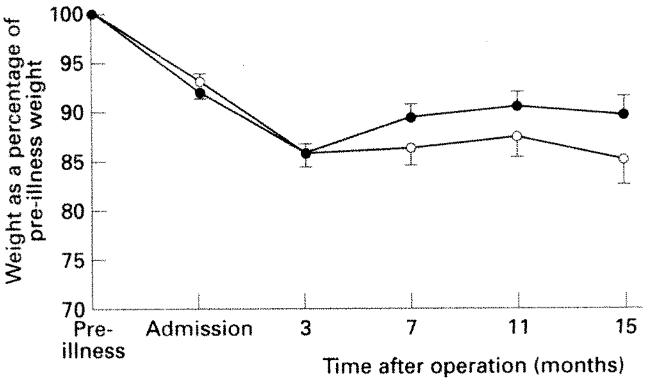

Fig. 1 Postoperative weight change as a percentage of pre-illness weight for all patients who underwent pancreatoduodenectomy for malignant disease of the pancreatic head region ($n = 115$): ○, standard Whipple procedure ($n = 49$); ●, pylorus-preserving pancreatoduodenectomy ($n = 66$). Values are mean(s.e.m.). Not significantly different at any time point

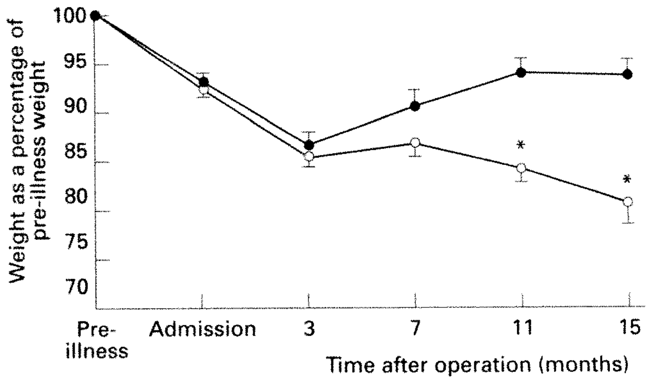

Fig. 2 Postoperative weight change as a percentage of pre-illness weight for patients who underwent pancreatoduodenectomy for malignant disease of the pancreatic head region ($n = 115$). ○, Patients with positive tumour status during follow-up ($n = 71$); ●, patients with negative tumour status ($n = 44$). Values are mean(s.e.m.). *$P < 0\cdot0001$ (Mann–Whitney U test)

Values are mean(s.e.m.). There were no significant differences between procedures for patients with positive or negative tumour status

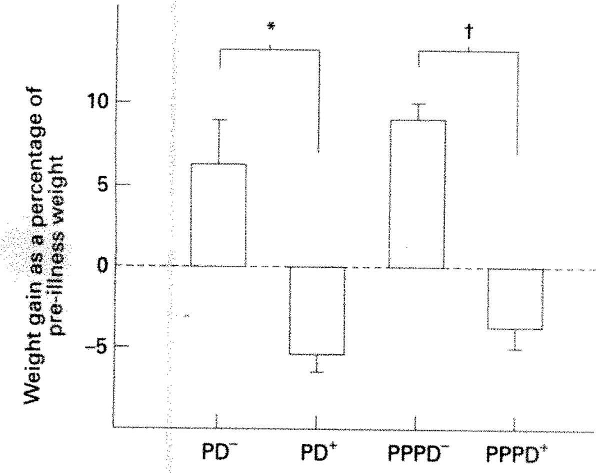

Fig. 4 Total weight gain (as a percentage of pre-illness weight) between 3 and 15 months after operation for the four different groups of patients who underwent pancreatoduodenectomy for malignant disease of the pancreatic head region ($n = 115$). PD$^-$, standard Whipple procedure, negative tumour status; PD$^+$, PD with positive tumour status; PPPD$^-$, pylorus-preserving pancreatoduodenectomy, negative tumour status; PPPD$^+$, PPPD with positive tumour status. Values are mean(s.e.m.). $^*P = 0{\cdot}0003$, $^\dagger P < 0{\cdot}0001$ (Mann–Whitney U test)

and PPPD, both in patients with negative tumour status and in those with positive tumour status. Patients with negative tumour status had a significantly better weight gain between 3 and 15 months after operation compared with those with a positive tumour status, after both types of resection (*Fig. 4*).

Discussion

In previous studies on weight gain after pancreatoduodenectomy, tumour-related factors such as the influence of non-radical resection or tumour recurrence were not evaluated[13,14,17]. In the present study tumour recurrence was defined as clinically evident tumour recurrence within 2 years of surgery. The authors are aware that a few more patients will eventually develop tumour recurrence during further follow-up. This will, however, hardly affect the weight curves during the first 15 months. The present series shows that tumour-positive status, defined as microscopic ingrowth into the resection margins and tumour recurrence, are important factors determining weight gain after pancreatoduodenectomy. These factors seem to be of more importance for postoperative weight gain than the type of surgical procedure carried out. Patients with a positive tumour status showed a significant decline in weight. At 15 years of operation patients with positive tumour status had lost 23 and 17 per cent of their usual weight, for standard and pylorus-preserving resection respectively. In none of the groups was mean pre-illness weight reached. At 15 months after operation patients with a negative tumour status regained 94 per cent of pre-illness weight. In an early study Braasch *et al.*[18] reported similar results in 28 patients after PPPD who regained a mean body-weight of 93 per cent of pre-illness weight[18]. In another study patients after PPPD regained 95 per cent of the weight that was lost before operation[19]. In both studies positive tumour status was not taken into account and a large proportion of the patients had undergone resection for chronic pancreatitis[18,19]. In a study by Zerbi *et al.*[13], weight at 6 months after operation was significantly better following PPPD than standard resection: 92 and 86 per cent of pre-illness weight respectively. Patients with tumour recurrence during these 6 months were not taken into account in this analysis[13].

PPPD has been reported to be a good alternative to the standard Whipple resection. Although some authors advise against PPPD for periampullary cancer[11,20], in most studies similar postoperative morbidity and mortality and 5-year survival rates are reported compared with the standard Whipple resection[10,14,21,22]. PPPD is therefore accepted in most centres as a standard resection for ampullary and periampullary cancer. Moreover, in the present series none of the patients with microscopically non-radical resection showed ingrowth into the duodenal resection margin.

Morbidity and mortality rates were no different for the two procedures, but the present series does show a shorter operating time, less peroperative blood loss and subsequently a lower transfusion need for the pylorus-preserving resection. In another study in which the authors investigated delayed gastric emptying after standard Whipple resection and PPPD, similar results were found[23]. These results may also be a reflection of the fact that most of the standard Whipple resections were performed at an earlier point in time. A learning curve might have played a role in these results. Another contributing factor is the different reconstruction that was used for pancreatoduodenectomies performed after 1993, using one jejunal loop, a single-layer pancreatic anastomosis and without placement of a transanastomotic drain in the pancreatic duct. Others, however, have reported similar advantages for PPPD[14,24].

The present series shows a slightly lower number of patients needing pancreatic exocrine supplementation after PPPD than after standard Whipple resection. Postoperative radiotherapy could cause pancreatic exocrine insufficiency, but in the present study a similar number of patients was treated with postoperative radiotherapy and chemotherapy after both procedures. Others have also reported a lower number of patients with pancreatic exocrine insufficiency after PPPD compared with standard pancreatoduodenectomy[17].

In conclusion, postoperative weight gain was no different for patients who underwent standard Whipple resection or PPPD in the first 15 months after resection. Tumour-related factors such as ingrowth into the resection margins and recurrence are probably more important with respect to weight gain in these patients than is the type of resection. Most patients, however, do not return to their pre-illness weight after either procedure.

---

Background Transient gastric stasis immediately after pylorus-preserving pancreatoduodenectomy (PPPD) is a common complication, but the cause remains unknown. Changes in gastric emptying were investigated in patients undergoing PPPD for periampullary malignancy.

Methods In 14 patients undergoing PPPD, liquid- and solid-phase gastric emptying were evaluated before and after operation (mean 38 (range 27–53) days after operation). Two pharmacological gastric-emptying tests were used: the acetaminophen test for liquid-phase emptying and the sulphamethizole capsule food test for solid-phase gastric emptying.

Results All patients exhibited delayed solid emptying but fairly good liquid emptying.

Conclusion Gastric function in the early postoperative period after PPPD is characterized by delayed solid-phase but good liquid-phase emptying.

Pylorus-preserving pancreatoduodenectomy (PPPD) was first reported by Watson[1] and reintroduced by Traverso and Longmire[2] in 1978; it has become the standard surgical procedure for benign or malignant periampullary lesions. Although this procedure eliminates the postgastrectomy symptoms that are common after the classical Whipple procedure, transient gastric stasis immediately after operation has been a frequent complication[3–6]. The cause of this complication remains unknown.

Some authors have measured gastric emptying some months after PPPD[7–9]; they showed recovery in the late postoperative period. However, there have been few reports of solid and liquid gastric emptying in the early postoperative period. Early function after operation is usually expressed clinically as the duration of nasogastric decompression or the inability to tolerate solid food.

Gastric emptying was measured using pharmacological tests at a mean of 38 days after PPPD. The indirect gastric emptying tests utilized two pharmacological markers: powdered acetaminophen (paracetamol), and pelletized sulphamethizole. The markers were ingested simultaneously with 250 ml water and the serum drug concentrations were assayed. These tests (the sulphamethizole capsule food test[10] and the acetaminophen test[11,12]) are based on the fact that absorption of the marker agents depends on the rate of gastric emptying[13,14]. Acetaminophen is emptied from the stomach with the water and pelletized sulphamethizole is dealt with as a solid by the stomach.

Patients and methods

From March 1992 to May 1993, 19 patients with periampullary lesions underwent PPPD in the authors' department. The operation included resection of the head of the pancreas, the duodenum distal to the first portion, a short segment of the proximal jejunum, the gallbladder and the common bile duct. Regional lymph node dissection around the common hepatic, coeliac and superior mesenteric arteries, and the abdominal aorta was also performed. The pancreatic remnant, common hepatic duct and the first portion of the duodenum were anastomosed to the jejunal loop in an end-to-side fashion, in this order. Five of the patients were excluded: three refused gastric emptying testing, one underwent PPPD without lymph node dissection and one required antidepressants in the postoperative period. The latter patient was excluded because of the possible influence of the antidepressants on gastric emptying.

Informed consent was obtained from all patients and the study was approved by the human research review committee of Nagoya University Hospital.

Preparation of sulphamethizole capsules

The sulphamethizole capsules were prepared according to the method of Asada *et al.*[10]. Chicken egg albumin (1·69 g) (Katayama Chemical, Tokyo, Japan), sulphamethizole (0·56 g) (Urocydal; Eizai, Tokyo, Japan), powdered acacia (0·38 g) (gum Arabic powder; Katayama) and distilled water (4·87 g) were mixed. The mixture was steamed for 8 min in a steel case until solidified. After it had cooled, 15 hard gelatin capsules (no. 1) were filled with this solid matter.

Gastric emptying tests

A combined direct gastric emptying test was performed to evaluate preoperative and postoperative function. The test was scheduled within 5 days of operation and at a mean of 38 (range 27–53) days after surgery.

After an overnight fast each patient was given 15 sulphamethizole capsules and 0·75 g acetaminophen (Napa; Astra Japan, Osaka, Japan) with 250 ml of warm (body temperature) water. The patients sat at ease and were prohibited from drinking, eating or smoking during the test. Venous blood samples were taken every 30 min until 4 h after ingestion. The blood samples were centrifuged at 3000 r.p.m. for 10 min, and the serum was stored at −20°C until assayed.

Measurement of drug concentration in the blood samples

Serum sulphamethizole concentrations were measured with a high-performance liquid chromatography system (HPLC). Serum

Paper accepted 24 November 1997

was mixed with a double volume of acetonitrile, shaken for 2 min and filtered (Millex-GV 0·2 μm; Millipore Products Division, Bedford, Massachusetts, USA). The filtrate (20 μl) was injected into the HPLC apparatus (Shimadzu LC-6A system; Shimadzu, Kyoto, Japan), which was equipped with an STR-ODS II column (Shimadzu). The mobile phase was a mixture of acetonitrile and 1 per cent acetic acid at 13:87 (v:v), which ran at a rate of 1 ml/min. The peaks of sulphamethizole appeared approximately 13 min after injection at room temperature. Sulphamethizole concentrations were calculated using the Chromatopack 6A system (Shimadzu) and a standard curve.

Serum acetaminophen levels were analysed by means of fluorescence polarization immunoassay (FPIA). Serum (50 μl) was placed in test tubes on the carousel of the fully automated FPIA apparatus (TDX; Dainabot, Tokyo, Japan). Reagents were supplied commercially as a kit (Dainabot).

Results were adjusted according to body-weight using the following formula: (adjusted drug concentration) = (analysis results) × (body-weight (kg))/60 (kg).

Statistical analysis

Results are expressed as mean(s.d.). Statistical analysis was performed with the paired Wilcoxon test. $P<0{\cdot}05$ was considered statistically significant.

Results

Clinical data

There were 14 patients (seven men and seven women) enrolled in the study with a mean age of 62·5 (range 41–73) years. All patients had periampullary malignancy diagnosed before operation (two papillary, five bile duct and seven pancreatic head cancers). Three patients with diffuse bile duct carcinoma also underwent combined PPPD and liver resection[15]. The mean length of the proximal duodenal remnant was 2·4 (range 1–4) cm.

There were four postoperative complications in four patients (anastomotic leakage, cholangitis, pancreatitis and inter-abdominal infection), but no hospital deaths. The mean duration of gastric decompression via tube gastrostomy was 11 (range 3–27) days. A liquid diet was commenced 16 (range 8–29) days after operation). Solid food was started 33 (range 20–50) days after surgery).

Solid- and liquid-phase gastric emptying

Solid-phase gastric emptying was delayed in the postoperative period (*Fig. 1*). The rise in the mean postoperative sulphamethizole concentration was slower, and the peak was lower and appeared later than in the preoperative period. The mean(s.d.) peak value was 3·58(1·40) μg/ml at 150 min before operation and 2·08(1·15) μg/ml at 180 min after operation. At each time point during the 4 h, the differences between preoperative and postoperative results were statistically significant ($P<0{\cdot}05$). In all patients the postoperative serum sulphamethizole concentration at 120 min was lower than the corresponding preoperative value (*Fig. 2*).

Differences in liquid-phase emptying were less pronounced (*Fig. 3*). Mean(s.d.) preoperative and postoperative peaks were 11·9(1·6) and 10·4(2·8) μg/ml at 60 min. The rise in the mean acetaminophen concentration was slower in the postoperative than in the preoperative period. However, differences were not significant ($P=0{\cdot}07$, $P=0{\cdot}07$ and $P=0{\cdot}96$ at 30, 60 and 90 min respectively), except at 120 min ($P<0{\cdot}01$). The individual changes at 60 min exhibited no apparent tendency toward delayed gastric emptying in the postoperative period (*Fig. 4*).

Discussion

PPPD has been reported to minimize postgastrectomy symptoms in patients undergoing resection of the head of the pancreas and the duodenum, by preserving gastric reservoir function[16]. The present authors have shown previously that oral caloric intake 6 weeks after operation is significantly better in patients undergoing PPPD than in those having classical pancreatoduodenectomy[17]. Post-

prandial plasma gastrin and secretin levels are similar in patients having PPPD and controls[18].

However, functional recovery of the preserved stomach and the first portion of the duodenum requires several days or weeks. Yeo and colleagues[19] showed delayed solid and liquid gastric emptying on the tenth postoperative day and documented the effectiveness of erythromycin for this problem. On the other hand, Hunt and McLean[8] reported normal solid and liquid gastric emptying in six of nine patients 3 months after PPPD. Williamson *et al.*[9] studied liquid and solid gastric emptying in 24 patients who had undergone PPPD and reported that late delay in gastric emptying was uncommon. In the present study gastric emptying was measured in 14 patients who had PPPD around the sixth postoperative week, and delayed emptying of solids with well recovered liquid emptying was found.

The different intervals between the operation and measurement of gastric emptying in the various studies may explain the variable results. This suggests that there is a pattern of recovery of gastric emptying after PPPD. Immediately after operation both phases of gastric emptying are disturbed. Liquid-phase gastric emptying recovers within several weeks. Finally, solid-phase gastric emptying recovers.

Physiologically, solids are pushed aborally with phasic motility of the distal stomach, and liquids flow through the pylorus with tonic contraction of the proximal stomach. This functional difference in gastric emptying may relate to the stepwise recovery of function after PPPD.

The precise cause of the dysfunction of gastric emptying after PPPD remains unknown. Many factors, including pancreatic fistula and perihepatic abscess[8,20], injury to the duodenal neurovascular supply[16,21], gastric atony secondary to decreased plasma motilin concentration[19,22] and transient torsion or angulation of the reconstructed alimentary tract[23], have all been proposed.

There have been no previous reports of the different disturbances in solid- and liquid-phase gastric emptying in the early period after PPPD. However, this kind of gastric emptying dysfunction is well known in patients with diabetic or postvagotomy gastroparesis, both of which result from impaired neural control[24–27]. In PPPD, the neural supply to the stomach is usually preserved, while the vagal branches to the pylorus and the first portion of the duodenum are sometimes injured. Dysfunction of the pylorus and duodenum may be a factor in delayed gastric emptying after PPPD.

In this study gastric emptying was evaluated by means of indirect pharmacological tests. Heading and colleagues[11] reported a significant correlation between the isotopic gastric emptying half-time and plasma acetaminophen concentration. A quick rise in the blood drug concentration suggests rapid gastric emptying. On the other hand, a slow ascent implies delayed gastric emptying[28,29]. This test has been used in patients who have undergone PPPD[23]. Sulphamethizole is a sulpha drug that is absorbed rapidly and almost completely when administered orally[30]. Asada *et al.*[10] pelletized sulphamethizole with egg albumin and used it as a marker of solid-phase gastric emptying. They reported that sulphamethizole absorption depended largely on the gastric emptying rate of the pellets[10]. Compared with dual-phase radioisotopic gastric emptying tests, which require a dual-head γ camera, this simple test is convenient and inexpensive.

In conclusion, the results of simple gastric emptying tests showed that liquid-phase gastric emptying had recovered and that solid-phase emptying was still disturbed 38 days after PPPD. This suggests a stepwise recovery of gastric emptying. Immediately after operation both liquid and solid phases of gastric emptying are disturbed. Liquid-phase emptying recovers within 2–5 weeks. Finally, solid-phase gastric emptying recovers approximately 3 months after operation. This type of gastric emptying disorder resembles that seen after vagotomy and in diabetic gastroparesis, both of which result from impaired neural control of the gastrointestinal tract.

Background Malnutrition is known to affect wound healing but it is not known with certainty whether or not postoperative hyperalimentation can reverse this defect. The present study was designed to examine the effects of recombinant human growth hormone (hGH) on left colonic anastomoses in malnourished rats.

Methods Experimental animals were allocated randomly into four groups. In groups 1 and 2 animals were fed with normal diet for 10 days before surgery. In groups 3 and 4 animals were fed with a low-protein diet. Left colonic anastomoses were performed in all animals. Following surgery, rats in groups 1 and 3 received hGH whereas rats in groups 2 and 4 were injected with saline as control. Bursting pressure and hydroxyproline levels on day 4 after operation were used to determine anastomotic healing.

Results Bursting pressure was lower in the malnourished rats than those fed with normal diet ($P < 0·05$). Bursting pressure was higher in normally fed rats which were given hGH. No significant differences could be noted between malnourished control rats and those receiving hGH.

Conclusion These results suggest that hGH strengthened the left colonic anastomoses in rats fed a normal diet, but could not reverse the negative effects of malnutrition on colonic anastomoses.

Anastomotic leakage after colonic resection is a serious complication with high morbidity and mortality[1,2]. Surgical technique, ischaemia, nutritional status of the patient, irradiation and presence of diabetes mellitus impair anastomotic healing[3,11].

Malnutrition is known to have a deleterious effect on wound healing, but it is not clear whether postoperative hyperalimentation can reverse this defect. The effects of duration of protein restriction and postoperative amino acid replacement on anastomotic healing are also unclear[4,6,8,11].

Previous studies in rats have shown that human growth hormone (hGH) (Genotropin; Pharmacia, Istanbul, Turkey) accelerates wound healing and strengthens colonic anastomoses[12–17]. The effect of hGH on colonic anastomosis in malnourished rats has not been studied previously. Thus, it may be hypothesized that hGH could overcome the negative effects of malnutrition on anastomotic healing.

The present study investigated the effect of hGH on left colonic anastomosis in malnourished rats that were fed with a low-protein diet for a short time.

Materials and methods

Forty male Sprague–Dawley rats weighing 220–260 g were allocated randomly into four identical groups. In groups 1 and 2 animals were fed with normal diet for 10 days before surgery (3·6 g/protein, 40 kcal per day). In groups 3 and 4 animals were fed with a low-protein diet (1·2 g protein, 40 kcal per day) for 10 days before surgery. All animals had free access to the standard laboratory diet and water after surgery. Before operation all animals were kept in separate cages and changes in weight were noted.

Surgical procedure

The animals were anaesthetized by an intramuscular injection of ketamine hydrochloride (50 mg per kg of body-weight). A midline laparotomy incision was made and a 1-cm segment of left colon was resected 3 cm proximal to the peritoneal reflection. The faecal contents were milked out and a standardized end-to-end anastomosis was performed with inverting 6/8 polypropylene sutures. The abdominal wall was closed with a single layer of 3/0 silk. After 24 h the animals were allowed to resume their respective diets.

In groups 1 and 3 rats were given hGH subcutaneously at the back of the neck in a dose of 2 mg per kg per day for 4 days beginning on the operation day. In groups 2 and 4 equivalent volumes of saline were injected.

Four days after operation the abdominal incision was reopened. The anastomotic segment was resected preserving the adhesions which were 2 cm proximal and 2 cm distal to the anastomotic line. The bursting pressure of the anastomotic segment was measured with a mercury manometer and a constant flow pump (Perfusor Secura FT; B. Braun, Germany). Following this procedure the bowel was opened longitudinally. The whole tissue in the area between 4 cm proximal and 4 cm distal to the anastomotic line was stored at −40°C for hydroxyproline determination. Hydroxyproline determination was performed by spectrophotometry at 560 nm by the technique described by Dekker *et al.*[18].

Data are expressed as mean(s.d.). Analysis of variance was used for statistical analysis and $P < 0·05$ was considered significant.

Results

One rat in group 3 and one from group 4 died on day 3 after surgery from sepsis resulting from anastomotic dehiscence.

Paper accepted 20 October 1997

Body-weight was constant in rats fed on a normal diet ($P > 0{\cdot}05$), but there was a fall of 15 per cent in the groups fed on a low-protein diet until surgery ($P < 0{\cdot}05$). Following surgery rats fed on a normal diet which received hGH had a 2 per cent increase in body-weight, but the groups receiving saline had a 2 per cent decrease in body-weight ($P < 0{\cdot}05$). Weight loss continued in malnourished rats after surgery (5 per cent in saline group, 3 per cent in hGH group) ($P < 0{\cdot}05$) (*Fig. 1*).

Bursting pressure of the anastomotic segments was lower in malnourished rats than in normally fed rats ($P < 0{\cdot}05$). In the normal diet groups, bursting pressure values in the hGH injected rats were 10 per cent higher than in the saline injected group ($P < 0{\cdot}05$). No significant difference existed between the hGH and saline groups of malnourished rats (*Table 1*).

In group 1, hydroxyproline levels were 9 per cent higher than in group 2 ($P > 0{\cdot}05$). There was no significant difference between the normal and malnourished rats which were injected with saline. No significant difference could be noted between hGH and saline groups among malnourished rats.

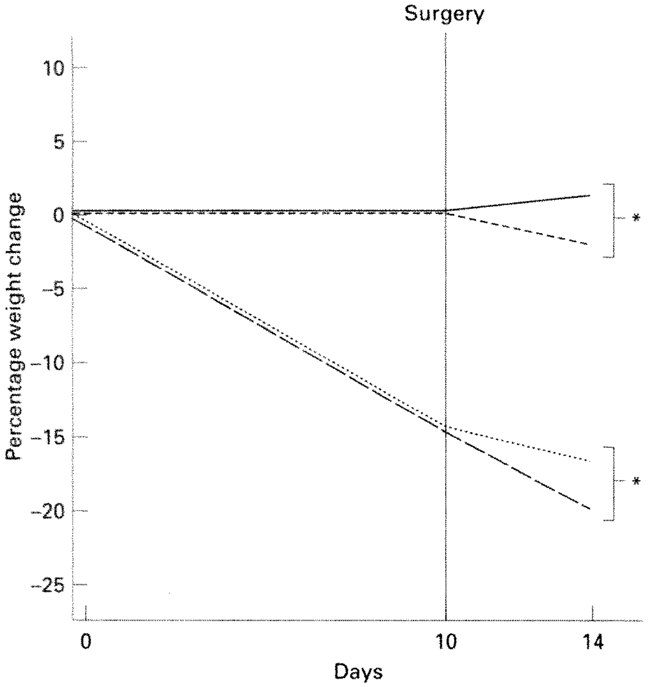

Fig. 1 Percentage weight change 10 days before and 4 days after surgery. Rats on normal diet receiving b-hGH (group 1, ———); rats on normal diet receiving saline (group 2, - - - -); protein-malnourished rats receiving b-hGH (group 3, ·····); protein-malnourished rats receiving saline (group 4, — —). $^*P < 0{\cdot}05$

Discussion

Delayed wound healing is seen in malnourished patients undergoing surgery[19]. Wound healing is inhibited by accelerated catabolism and protein consumption in the early postoperative period[6]. Previous experimental studies have reported the detrimental effects of malnutrition on the healing of colonic anastomoses[4,6,8,11]. Ward *et al.*[6] have reported that anastomotic healing was impaired in rats which lost 12·5 per cent of their body-weight resulting from protein restriction. Likewise, Daly *et al.*[4] reported that colonic bursting pressures decreased by 17·5 per cent during a week-long protein restriction in rats. In the present study, the effect of postoperative hGH on anastomotic healing was examined by creating a similar model of protein malnutrition to that observed in surgical patients. As weight loss in surgical patients is usually about 12·5 per cent[20], a similar condition was created in the present study. As a result, anastomotic healing was impaired in rats with a weight loss of 15 per cent. The most likely reason for impairment is the effect of protein restriction on amino acid bioavailability.

Growth hormone accelerates cell proliferation and enhances amino acid efflux into the cells for protein synthesis or gluconeogenesis[21–23]; it also provides protein anabolism by enhancing nitrogen uptake and preventing the loss of protein[22–26], and is known to be an effective anabolic hormone preventing postoperative weight loss[15,16]. In this study hGH intake led to significantly increased body-weight when control animals were compared with the normal diet groups, but in malnourished rats weight loss occurred both in the hGH and saline-treated groups.

In the present study bursting pressure increased with hGH in normally fed rats; these results are similar to those of Christensen *et al.*[12–16]. An anastomoses is at its weakest on days 2 and 3 when the repair of new collagen cannot be completely organized instead of the collapsed old collagen[27]. In this study anastomotic healing was evaluated on day 4 after surgery. The fact that bursting pressure significantly increased in rats on a normal diet compared with controls suggests that hGH is effective in the early phase of healing. The mechanism of action of hGH on the healing of anastomosis in the early phase has not been explained completely as the anastomosis is weakest in the early postoperative period. The probable causes of the rapid response to hGH stimulation are fibroblast stimulation and hGH receptors in rat colon[16,28]. The effects of hGH are related to insulin like growth factor (IgF) I produced in liver, IgF-I receptors in the

Table 1 Bursting pressure and hydroxyproline levels of left colonic anastomoses on day 4 after surgery in rats on a normal diet receiving b-hGH (group 1); rats on a normal diet receiving saline (group 2); protein-malnourished rats receiving b-hGH (group 3); and protein-malnourished rats receiving saline (group 4)

	Normal rats			Malnourished rats

gastrointestinal tractus and hGH receptors recently discovered in the rat colon[13,14,29,30]. Christensen *et al.*[15,16] reported in their consecutive studies that hGH not only influences cells that have been stimulated before the operation but also during the period of healing itself.

Contrary to expectations, hGH could not influence anastomotic healing in rats which lost 15 per cent of their body-weight. The possible reasons for this may be: (1) the short duration of treatment; (2) the standard single-dose therapy; and (3) protein deprivation. The stimulatory effects of hGH on wound and anastomotic healing and its relation to dose and time have been reported by various authors[3,12–15,17]. At present the effects of hGH on anastomotic healing are unclear and this fact necessitates further studies on the efficacy of hGH in malnutrition.

The present study established that hGH strengthened left colonic anastomoses in well nourished rats but did not reverse the negative effects of malnutrition on anastomotic healing. Further detailed studies with different durations and doses are necessary to determine whether hGH can improve anastomotic healing.

Long-term results of femorotibial bypass with vein or polytetrafluoroethylene

R. D. SAYERS, S. RAPTIS, M. BERCE and the late J. H. MILLER

Department of Vascular Surgery, Royal Adelaide Hospital, North Terrace, Adelaide, South Australia
Correspondence to: Mr R. D. Sayers, Department of Vascular Surgery, Leicester General Hospital, Gwendolen Road, Leicester LE5 4PW, UK

Background This was a retrospective review of the long-term results of femorotibial bypass using autologous vein and polytetrafluoroethylene (PTFE) over 24 years.

Methods Some 518 patients who underwent 635 femorotibial bypass grafts were studied. Outcome measures analysed included primary and secondary graft patency, limb salvage rates and death.

Results Overall primary and secondary graft patencies were 62 and 67 per cent respectively at 12 months, and 44 and 48 per cent at 24 months. For vein grafts, the primary and secondary patencies were 63 and 66 per cent at 12 months, and 54 and 56 per cent at 24 months. For PTFE grafts, the primary and secondary patencies were 48 and 54 per cent at 12 months, and 31 and 37 per cent at 24 months. Limb salvage and patient survival rates were 81 and 84 per cent at 12 months, and 73 and 74 per cent at 24 months. Primary and secondary graft patencies for vein were significantly better than for PTFE ($P = 0{\cdot}0001$). There was no difference in patency between reversed and *in situ* grafts.

Conclusion Femorotibial bypass can produce excellent long-term results. Vein remains the conduit of choice but in the absence of vein acceptable results can be achieved with PTFE.

Femorotibial bypass is an acceptable technique for revascularizing a critically ischaemic leg and avoiding a major amputation[1–5]. It can be a demanding operation with a long learning curve and good results may be achieved only by surgeons who perform the operation regularly. Autologous saphenous vein has the best patency and limb salvage rates. Many patients do not have suitable or available saphenous vein. The use of prosthetic grafts remains controversial despite enthusiasts who claim good results for polytetrafluoroethylene (PTFE) bypass to distal sites[6]. Many surgeons advocate the use of adjuvant techniques such as vein cuffs, patches and fistulas[7,8]. The Royal Adelaide Hospital has an extensive experience of femorotibial bypass with both vein and PTFE over nearly a quarter of a century. This paper presents the long-term results of this experience.

Patients and methods

All patients who had femorotibial bypass between August 1971 and December 1995 were entered on a computerized vascular database. This enabled evaluation of the outcome of surgery and follow-up. The Royal Adelaide Hospital is a teaching hospital in South Australia and has a wide catchment area extending into New South Wales and the Northern Territories with a population of over one million. Patients were admitted for non-invasive assessment, control of medical risk factors and angiography. The operation was usually performed under general anaesthesia and completion angiography was performed routinely. The technique of forming a Miller vein cuff has been reported previously[7]. Follow-up was by regular clinical examination and ankle–brachial pressure measurement. Limited duplex graft surveillance[9] was available during the later years but some patients lived too far away to be able to participate in any useful surveillance programme. In these cases outcome was determined by telephone interview with the patient and/or general practitioner.

Statistical analysis

Graft patency is reported according to the recommendations of the ad hoc committee of the Society of Vascular Surgery[10]. Primary graft patency is defined as uninterrupted patency with no procedures performed on the graft or its anastomoses. Secondary patency requires that flow is restored through most of the original graft including at least one of its original anastomoses. Actuarial patency curves were computed using the Kaplan–Meier method[11]. Multivariate analysis was performed on risk factors; however, the fact that some patients had multiple observations (i.e. several operations on one leg or operations on both legs) necessitated the use of the Wei–Liu–Weissfeld adaptation of the Cox proportional hazards regression procedure for comparison of risk factors and graft types and the multivariate analysis[12].

Results

Between August 1971 and December 1995, 518 patients had 635 femorotibial bypass procedures. The patient demographics are shown in *Table 1*. Some 361 procedures (57 per cent) were primary and 274 (43 per cent) were secondary in legs that had already undergone a distal graft. The graft details are shown in *Table 2* and inflow and outflow arteries are shown in *Table 3*.

Table 1 Patient demographics

No. of patients	518
Men	368 (71)
Women	150 (29)
Median (range) age (years)	72 (40–102)
Risk factors	
Ischaemic heart disease	248 (48)
Diabetes mellitus	187 (36)
Hypertension	200 (39)
Current or ex cigarette smoker	306 (59)

Values in parentheses are percentages

Paper accepted 4 January 1998

Graft patency rates are shown in *Fig. 1*, and limb and patient survival rates in *Fig. 2*. The primary and secondary graft patencies were 62 and 67 per cent respectively at 12 months, and 44 and 48 per cent at 24 months. For vein grafts, the primary and secondary patencies were 63 and 66 per cent at 12 months, and 54 and 56 per cent at 24 months. For PTFE grafts, the primary and secondary patencies were 48 and 54 per cent at 12 months, and 31 and 37 per cent at 24 months (*Fig. 3*). Limb salvage and patient survival rates were 81 and 84 per cent at 12 months, and 73 and 74 per cent at 24 months. There was a significant difference between primary and secondary vein and PTFE graft patency (both $P = 0{\cdot}0001$). In PTFE grafts there was no significant difference between cuff *versus* patch or direct suture for primary and secondary patency ($P = 0{\cdot}75$). There were no significant differences in primary or secondary patency between reversed and *in situ* grafts ($P = 0{\cdot}54$) (*Fig. 4*).

Discussion

Patients in this study were typical of those in other series; most had critical leg ischaemia although 21 patients (4 per cent) had severe claudication. An aggressive policy of femorotibial reconstruction was pursued in patients with severe ischaemia. This included re-do operations (43 per cent) in patients with blocked femoropopliteal or femorotibial grafts[13]. Patients usually had the operation on the first available daytime list which allowed 24–48 h for

an anaesthetic opinion and to treat any concurrent chronic medical disease. Patients who had no prospect of walking again because of dementia, severe arthritis, limb contractures or tissue necrosis extending into the weight bearing area of the foot were offered primary amputation.

Although ipsilateral long saphenous vein was used whenever available, only 40 per cent of patients in this series had a vein bypass. Arm vein was only used in 4 per cent of patients and only 2 per cent had contralateral long or short saphenous vein bypass. During this study, duplex assessment and vein mapping was not available. The introduction of this facility has increased the rate of vein utilization. In addition, the increasing prevalence of methicillin-resistant *staphylococcus aureus* infections has led to a more aggressive policy of using saphenous vein from the contralateral leg and also arm vein[14].

The results in this series are similar to others[5,15,16] in patients with severe ischaemia: limb salvage 81 and 73 per

cent at 12 and 24 months respectively and mortality rate 16 and 26 per cent at 12 and 24 months. As in other studies, patency in vein grafts was superior to that of PTFE, although there was no difference between reversed and *in situ* vein grafts. It is recognized that the long-term outcome in patients with severe leg ischaemia is poor; after 1 year, 25 per cent will have had an amputation and 25 per cent will have died[1]. The findings in this study are similar; at 5 years, the amputation rate was just below 40 per cent with a mortality rate of just under 70 per cent.

An aggressive policy of secondary femorotibial reconstruction has been followed using PTFE down to the ankle, if necessary, to achieve limb salvage. The majority of the PTFE grafts were fashioned in conjunction with a Miller vein cuff (80 per cent), with a vein patch or direct suture being the preferred technique in the remainder. The authors have previously reported superior patency rates for PTFE with a vein cuff to the below-knee popliteal artery[17]. In this non-randomized long-term review, there was no significant difference in patency for cuff *versus* patch or direct suture. The addition of a vein cuff can make a tibial anastomosis easier and preserves run-off should the graft thrombose. This allows easier surgical thrombectomy or thrombolysis.

The choice of vessel for the distal anastomosis was based on angiographic evidence of the most proximal disease-free vessel with good run-off into the distal circulation. Although pedal arch patency has been shown to be important for graft patency, its absence did not exclude patients from undergoing revascularization. The majority of grafts were to a calf vessel although 11 per cent had an anastomosis to the tibioperoneal trunk, if suitable. In most cases, there was only a single vessel run-off from the tibioperoneal trunk. Completion angiography was used routinely to exclude technical errors at the distal anastomosis.

Graft surveillance was difficult because of the geographical distances involved for many patients. A formal graft surveillance programme did not exist, although many local patients had 6-monthly duplex scans. A more rigorous and complete surveillance programme might have improved graft patency.

Femorotibial bypass can produce excellent results in patients with severe ischaemia. Autologous vein bypass produces the best results but acceptable results can be achieved with PTFE and a vein cuff, if vein is not available.

Provision of training in carotid surgery does not compromise patient safety

A. R. NAYLOR, M. M. THOMPSON, K. VARTY, R. D. SAYERS, N. J. M. LONDON and P. R. F. BELL

Department of Surgery, Clinical Sciences Building, PO Box 65, Leicester Royal Infirmary, Leicester LE2 7LX, UK
Correspondence to: Mr A. R. Naylor

Background Vascular surgeons perceive that carotid endarterectomy carries a higher risk of stroke if performed by a surgical trainee. Accordingly, some trainees consider that they receive a less than adequate training in carotid surgery before taking up a consultant position. The aim of this study was to establish whether the stroke rate was adversely affected if carotid endarterectomy was performed by a surgical trainee under consultant supervision.

Methods This was a prospective study of 151 consecutive patients undergoing carotid endarterectomy between 1 January and 31 December 1996 using a standardized technique including intraoperative and postoperative transcranial Doppler monitoring and completion angioscopy.

Results The overall mortality and/or disabling stroke rate was 0·7 per cent (one of 151 patients), whereas the mortality and/or any stroke rate was 1·3 per cent (two of 151). Surgical trainees performed 82 of 151 carotid endarterectomies, with a mortality rate of 1 per cent and a mortality and/or any stroke rate of 2 per cent. There was no significant difference in the incidence of retained thrombus or intimal flaps between trainees and consultants as detected by angioscopy.

Conclusion Vascular surgical trainees can receive a comprehensive training in carotid artery surgery without incurring an unacceptable increase in operative risk.

Until the early 1990s, carotid endarterectomy was essentially a consultant-only procedure so as to minimize the operative stroke risk in the relatively small number of patients treated in the UK. However, following publication of the European Carotid Surgery Trial (ECST) and the North American Symptomatic Carotid Endarterectomy Trial (NASCET)[1,2], there has been a rapid increase in the annual number of carotid endarterectomies performed in the UK which, in Leicester, equated to a near sevenfold rise between 1990 and 1996.

In order that this large increase in workload is matched by an ongoing commitment towards minimizing the initial operative risk (and therein the overall clinical effectiveness of the operation) it is essential that a newly appointed consultant vascular surgeon has received comprehensive training in carotid surgery. There is still a genuine concern among some vascular surgeons that, by taking their trainee through the operation, an inevitable and unacceptable increase in operative morbidity will be incurred.

A prospective audit of the 30-day morbidity and mortality rates following carotid reconstruction for occlusive disease was analysed in a consecutive series of 151 patients. The aim was to see whether carotid endarterectomy performed by vascular surgical trainees was associated with an unacceptably higher operative risk.

Patients and methods

This prospective study included 151 consecutive patients undergoing carotid endarterectomy between 1 January and 31 December 1996.

Operative technique

Aspirin therapy was not stopped before surgery. All carotid reconstructions were performed under normocarbic, normotensive anaesthesia and systemic heparinization (5000 units) in a standard manner. A shunt (Pruitt–Inahara) was employed routinely, the proximal and distal intimal steps were tacked down with 7/0 polypropylene and all arteriotomies were closed with a collagen-impregnated Dacron patch (Vascutek, Glasgow, UK). If carotid bypass was required, this was performed using a segment of reversed saphenous vein harvested from the groin.

The operation was performed by a consultant vascular surgeon or by a specialist vascular trainee or overseas clinical vascular fellow. All trainees had completed at least 3 years of higher surgical training and were within 2 years of completing specialist vascular training. Operations were specifically undertaken by a consultant if they were an emergency referral (e.g. for crescendo transient ischaemic attacks (TIAs)) or if the patient was referred by a consultant surgeon from another health district. Otherwise there was no systematic policy for allocating trainee or consultant procedures.

Trainees in this institution commence carotid surgery by first performing individual phases of the operation such as carotid dissection, shunt insertion, endarterectomy and patch closure. Thereafter the trainee is permitted to perform an increasing amount of the procedure until the consultant is happy to delegate the full operation. Accordingly there is an element of case selection in that a less experienced trainee would not be allowed to perform the operation if preoperative studies suggested distal disease extension, but such a patient would be suitable for teaching a more experienced trainee. For the purposes of this study, therefore, the operation was attributed to a trainee only if he or she performed the entire procedure. If the consultant performed the operation or if the trainee did only part of it (e.g. the dissection phase), the operation and any complications were attributed to the supervising consultant.

Perioperative monitoring

Blood flow velocity in the middle cerebral artery blood (MCAV) was monitored continuously in patients with an accessible

Paper accepted 1 December 1997

temporal window using transcranial Doppler (TCD) ultrasonography and a 2-MHz fixed-head probe system (Scimed, Bristol, UK). The surgeon was thereafter permitted to take any appropriate action to ensure optimal clinical outcome, for example embolization during dissection warned of an unstable plaque and permitted early internal carotid artery (ICA) clamping[3], while shunt malfunction (kinking, embolization, low flow) was immediately identified and corrected. The policy was to maintain a mean MCAV of 15 cm/s or more throughout the procedure, which on occasion required a therapeutic increase of arterial blood pressure by the anaesthetist[4].

Following endarterectomy and before complete closure of the patch, the shunt was removed and the carotid vessels were flushed and irrigated with heparinized saline and then reclamped. The lumen was inspected with a flexible fibreoptic hysteroscope to identify any residual technical error[5]. Policy was to remove any fragments of luminal thrombus and repair any intimal flap greater than 3 mm. Where necessary, an estimate of sizing of any luminal abnormality was done by comparison with the 2-mm diameter forceps that can be passed down the instrument channel of the hysteroscope.

Postoperative care

Patients recovered from anaesthesia in the operating theatre and were transferred to the high dependency unit where the TCD probe was reapplied to monitor ipsilateral MCAV for 10 min every 30 min for the next 6 h. In previous studies the authors have shown that embolic signals detected in the early postoperative phase are exclusively particulate[6], that sustained postoperative embolization is highly predictive of stroke as a result of carotid thrombosis[7,8] and that selective intervention with Dextran 40 therapy can reduce the risks of progression to carotid thrombosis[9]. Accordingly, any patient who had 25 or more emboli detected during any 10-min interval of monitoring was commenced on an incremental intravenous infusion of Dextran 40, starting at 20 ml/h. If the rate of embolization did not diminish, the infusion was gradually increased by 5 ml/h every 10 min to a maximum of 40 ml/h. Once the Dextran infusion rate was stabilized, it was continued at that dose for a further 12 h.

All patients were discharged home on aspirin (150 mg daily), usually on the fifth postoperative day, and all were reviewed 4–6 weeks later in the vascular clinic.

Results

Table 1 summarizes the patient demographics for the two study groups. There was no significant difference in either age or mode of presentation except that a consultant operated on all patients who presented with crescendo TIAs. Similarly, there was no significant difference in the patterns of concurrent disease.

Table 1 Patient demographics

	Operated on by vascular trainee ($n = 82$)	Operated on by consultant ($n = 69$)
Median age (years)*	68 (66–70)	67 (65–70)
Presentation†		
Stroke	32 (39)	25 (36)
TIA or amaurosis fugax	38 (46)	37 (54)
Asymptomatic	12 (15)	7 (10)
Urgent procedure	0 (0)	5 (7)
Concurrent disease†		
Hypertension	47 (57)	44 (64)
Angina pectoris	23 (28)	16 (23)
Previous MI	20 (24)	15 (22)
Diabetes mellitus	14 (17)	10 (14)

Values in parentheses are *95 per cent confidence interval and †percentages. TIA, transient ischaemic attack; MI, myocardial infarction

Table 2 Extent of carotid disease

	Operated on by vascular trainee	Operated on by consultant
Symptomatic patients		
Unilateral stenosis > 70%	45 (64)	40 (65)
Bilateral stenoses > 70%	12 (17)	13 (21)
Stenosis > 70%, contralateral occlusion	13 (19)	9 (15)
Total	70 (100)	62 (100)
Asymptomatic patients		
Unilateral stenosis > 70%	2	1
Bilateral stenoses > 70%	6	2
Stenosis > 70%, contralateral occlusion	4	4
Total	12	7

Symptomatic patients comprised 85 per cent of the operative workload of the trainees and 90 per cent of procedures performed by a consultant (*Table 2*). Overall, one-third of the symptomatic patients in the trainee- and consultant-operated groups had preoperative evidence of severe bilateral carotid artery disease. Almost one-fifth of the trainee operations were on symptomatic patients with a contralateral carotid occlusion (*Table 2*).

Some 144 patients (95·4 per cent) underwent a standard carotid endarterectomy, while seven needed carotid bypass (trainee, one; consultant, six). Carotid bypass was performed because of excessive kinking or looping of the distal ICA in five patients, and in two the residual arterial wall was very thin after endarterectomy and considered potentially unsafe. A further three patients (trainee, one; consultant, two) underwent formal shortening of the carotid bifurcation.

A consultant did not have to assume the role of principal surgeon in any operation that had been assigned from the outset to an experienced trainee.

Perioperative quality control

An accessible temporal window was present in 94 per cent of patients. TCD ultrasonography identified four patients with shunt malfunction. Three suffered inadvertent kinking of the shunt which was immediately recognized and corrected (trainee, two; consultant, one). In a further patient (consultant operation), ultrasonography indicated that the external carotid artery was the principal source of collateral blood supply to the brain. Accordingly the shunt was inserted into the external carotid while endarterectomy was performed.

All patients underwent completion angioscopy except for six of the seven undergoing carotid bypass. Angioscopic assessment was entirely normal in 95 per cent trainee procedures and in 94 per cent of consultant operations. A residual luminal thrombus was retrieved following one trainee endarterectomy and two consultant operations. Similarly, an intimal flap (greater than 3 mm) was detected and repaired in three and two operations respectively.

A total of 141 patients (93·4 per cent) underwent serial postoperative TCD monitoring. Of the ten not monitored after operation by ultrasonography (usually because of an inaccessible cranial window), none of the patients operated on by trainees but two in the consultant group

Table 3 Postoperative morbidity

	Operated on by vascular trainee ($n=82$)	Operated on by consultant ($n=69$)
Death or major stroke	1 (1)	0 (0)
Non-fatal minor stroke	1 (1)	0 (0)
Treatment for hypertension > 24 h	5 (6)	4 (6)
Heart failure	2 (2)	0 (0)
Treatment of arrhythmia	2 (2)	0 (0)
Unstable angina or myocardial infarction	1 (1)	2 (3)
Drainage of neck haematoma	2 (2)	4 (6)
Wound infection	2 (2)	1 (1)
Transfusion for anaemia	1 (1)	1 (1)
Pneumonia	1 (1)	0 (0)

were started on a Dextran infusion on the instructions of the operating consultant. Overall, three of 77 (4 per cent) of trainee operations monitored by ultrasonography developed sustained postoperative embolization which ceased following Dextran 40 therapy, compared with three (5 per cent) of 64 in the consultant group.

Perioperative morbidity and mortality

There was no significant difference in the 30-day morbidity and mortality rates between the two groups (*Table 3*). Eighteen patients (22 per cent) operated on by a trainee suffered some degree of morbidity compared with 12 (17 per cent) of the consultant operations.

Only one patient (trainee operation) suffered a fatal stroke following a computed tomography-verified intracranial haemorrhage on day 3. One other patient (trainee operation) suffered a non-fatal minor stroke with complete recovery.

Thus the overall mortality and/or rate of disabling stroke in 1996 was 0·7 per cent, whereas the mortality and/or any stroke rate was 1·3 per cent. Trainees performed 82 of 151 carotid endarterectomies with a mortality and/or disabling stroke rate of 1 per cent and a mortality and/or any stroke rate of 2 per cent. Consultants performed 69 carotid endarterectomies with no strokes or deaths occurring within 30 days of operation.

Discussion

The clinical effectiveness of carotid endarterectomy is inextricably linked to the initial operative risk. The lower the initial stroke risk, the greater the long-term benefit. The international trials reported a 5–7 per cent overall operative risk but despite this, carotid endarterectomy still conferred a 45 per cent relative risk reduction in the long-term stroke rate, when compared with best medical therapy alone. If the operative risk could be reduced to zero, the overall relative risk reduction would increase to 75 per cent[1,2]. Thus, centres with a higher operative stroke risk incur greater rehabilitation costs, prevent fewer strokes and may even become ineffective in terms of cost and/or clinical benefit. Moreover, surgeons must concede that the beneficial effects of carotid endarterectomy were proven in trials that allowed only surgeons with the lowest morbidity to participate. As a consequence, the ECST and NASCET results may not be applicable to all surgeons, all patients and all centres. For example, 47 (29 per cent) of 164 surgeons who applied to enter patients into the Asymptomatic Carotid Atherosclerosis Study were not approved following scrutiny of their centre's annual workload and track record[10]. This might explain why Medicare beneficiaries undergoing carotid endarterectomy at the same time as the NASCET study was being performed had an operative mortality rate of 3 per cent compared with only 0·6 per cent in NASCET[11].

The prevention of operation-related stroke therefore remains the goal of all vascular surgeons. The overall stroke risk is probably unrelated to anaesthetic practice[12] and the majority are due to inadvertent technical error[13]. Controversies about the role of temporary shunting, patch angioplasty, tacking sutures, quality control and perioperative monitoring persist, although relatively few studies have tried to standardize these and evaluate the impact of operative experience on outcome. There is evidence that surgeons who perform relatively few endarterectomies have a significantly higher stroke and/or death rate than more experienced colleagues[14]. Patients operated on by newly appointed consultant surgeons may be at a particular disadvantage.

This study has shown that vascular trainees can perform carotid endarterectomy with an acceptably low death and/or disabling stroke rate, in accordance with other similar studies[15,16]. An alternative conclusion might be that the study has simply confirmed that patients remain safer in the hands of a consultant surgeon. While this may well be the case, this study has shown that trainees' results can be equal to or better than those reported in the ECST or NASCET. Those who continue to assert that carotid endarterectomies must always be performed by a consultant surgeon must ask how they expect carotid surgeons of the future to be trained.

The low overall morbidity rate can be attributed to obsessional attention to detail, together with early recognition and correction of inadvertent technical error through the serial adoption of quality control and selected perioperative monitoring techniques[6–9]. In this respect, it was rewarding to observe that the incidence of technical error (as diagnosed by angioscopy) was no different between trainee and consultant-led procedures[17].

Exposure to a comprehensive carotid training programme appears to be variable. Recent evidence suggests that up to 90 per cent of vascular trainees in the UK have performed fewer than 20 carotid endarterectomies under consultant supervision, and 50 per cent performed fewer than ten. One-seventh of trainees had performed no carotid endarterectomies at all (J. H. N. Wolfe, data from the *1997 Annual Report of the Association of Surgeons of Great Britain and Ireland*). Even allowing for the effect of relative experience and stage of training, these data suggest that a significant number of surgeons approaching their first consultant post will probably have little carotid surgery experience. The system of training employed at this institution allows trainees of all grades to acquire progressively the operative skills they require. As a trainee becomes more proficient, it is essential that the supervising consultant adopts a less interventional role. The latter is one of the most difficult roles to balance but contributes towards a comprehensive training in carotid surgery.

The role of carotid endarterectomy has been proven unequivocally in selected patients, but surgeons must continue to strive to reduce operative risk. In this way the clinical and cost effectiveness of the procedure will increase. This not only entails attention to operative technique and avoiding inadvertent technical error, but also requires a renewed commitment to training the vascular surgeons of the future.

Thermotolerance induces heat shock protein 72 expression and protects against ischaemia–reperfusion-induced lung injury

Background Ischaemia–reperfusion injury is mediated by neutrophil–endothelial interaction. Induction of heat shock proteins attenuates neutrophil–endothelial interactions. The aim of this study was to determine whether thermal preconditioning could have a protective effect on neutrophil-mediated lung injury in an animal model of lower torso ischaemia–reperfusion.

Methods Sprague-Dawley rats were randomized into: control, ischaemia–reperfusion, and ischaemia–reperfusion preconditioned with hyperthermia groups. Ischaemia–reperfusion injury was induced by infrarenal aortic clamping for 30 min and reperfusion for 120 min. Thermotolerance was induced by raising the core body temperature to 40·5–41·5°C for 15 min, 18 h before ischaemia–reperfusion. Wet:dry lung (W:D) weight ratio, bronchoalveolar lavage protein (BAL_{prot}) concentration, tissue myeloperoxidase (MPO) activity and bronchoalveolar lavage polymorphonuclear neutrophil (BAL PMN) count were measured. Heat shock protein 72 (hsp72) expression in lung, intestine and mesentery was measured using Western immunoblotting.

Results Ischaemia–reperfusion resulted in a significant increase in tissue oedema (W:D weight ratio) and BAL_{prot} concentration. In addition there was a marked increase in tissue neutrophil infiltration (MPO activity, BAL PMN concentration). Preconditioning with hyperthemia resulted in increased expression of hsp72 and significantly reduced tissue oedema and neutrophil infiltration.

Conclusion Thermal preconditioning protects against neutrophil-mediated ischaemia–reperfusion-induced lung injury, possibly by increasing the expression of heat shock proteins.

Reperfusion of a large mass of ischaemic tissue, such as the lower torso, may induce systemic inflammatory reactions[1]. Severe and sometimes fatal pulmonary complications secondary to this inflammatory process have been described[2,3]. A key event in the pathogenesis of ischaemia–reperfusion injury is thought to be the interaction between activated neutrophils and the vascular endothelium[4–7]. Ischaemia–reperfusion results in upregulation of surface adhesion molecules and activation of circulating neutrophils which in turn adhere to the vascular endothelium and release oxidants and proteases which cause microvascular injury[8,9].

The heat shock or stress response refers to the process whereby stressful stimuli (e.g. hyperthermia) induce a transient resistance of the cells to subsequent noxious stimuli[10]. This resistance to oxidative stress is associated with an increased synthesis of highly conserved proteins called the heat shock proteins. Animal studies have shown that the heat shock response is protective against ischaemia–reperfusion-induced injury in the heart[11–13], small intestine[14], skeletal muscle[15] and kidneys[16]. The aim of this study was to evaluate the efficacy of thermotolerance in preventing ischaemia–reperfusion-induced lung injury in an animal model of lower torso ischaemia and reperfusion.

Materials and methods

Animal preparation

All animal procedures were carried out under licence from the Department of Health. Twenty-one adult male Sprague-Dawley rats weighing 350–400 g were randomized into three groups: control, ischaemia–reperfusion and a thermotolerant ischaemia–reperfusion group. Thermotolerance was induced 18 h before experimentation by increasing the core body temperature of the animals to 40·5–41·5°C by partial immersion in a water bath (Grant Instruments, Cambridge, UK) for 15 min[17] under anaesthesia with inhalational halothane (May and Baker, Dagenham, UK).

At the time of experimentation, animals were anaesthetized with inhalational halothane. The right internal jugular vein was catheterized for administration of heparin. All animals were maintained supine and core body temperature was monitored for the duration of the experiment by rectal probe (Hewlett-Packard, Boeblingen, Germany).

Aortic occlusion and reperfusion

Anaesthetized rats, including controls, underwent a midline laparotomy. In the ischaemia–reperfusion and ischaemia–reperfusion with hyperthermia groups the infrarenal abdominal aorta was exposed and after heparinization with 400 units heparin per kg body-weight a clamp was placed above the aortic bifurcation for 30 min. In control animals the aorta was exposed but not clamped. After 30 min of lower torso ischaemia the aortic clamp was removed through the previous laparotomy incision. Some 2 h after removal of the clamp the animals were killed.

Bronchoalveolar lavage

After sternotomy the left bronchus was clamped. Bronchoalveolar lavage (BAL) of the right lung was performed with 2 ml

---

Presented to the 84th meeting of the Surgical Research Society, Birmingham, UK, June 1996 and published in abstract form as *Br J Surg* 1996; **83**: 1646
Paper accepted 16 November 1997

saline containing 0·07 mol/l ethylenediamine tetra-acetic acid. This was repeated three times. The combined lavage of approximately 4 ml was centrifuged at 1500*g* for 20 min at 4°C and frozen at − 20°C. BAL fluid was subsequently used for measurement of protein concentration (BAL_{prot}) by the spectrophotometric dye method of Lowry *et al.*[18].

Neutrophil count in BAL fluid (BAL PMNs) was used as a measure of pulmonary neutrophil influx and microvascular leakage. This was carried out by Diff-Quick staining of a representative sample of BAL fluid and consecutive counting of neutrophils per high power field.

Wet:dry lung weight ratio

Lung wet:dry (W:D) weight ratios were used as a measure of pulmonary oedema. The W:D weight ratio of the right lower lobe was calculated after weighing the freshly harvested organ, heating at 90°C in a gravity convection oven and repeatedly weighing the residuum until its weight became constant.

Myeloperoxidase assay

Myeloperoxidase (MPO) is a haem-containing enzyme which is found in neutrophils, and so can be used as an indirect measure of tissue neutrophil infiltration[19]. The right ventricle was cannulated with a 25-G needle and the right pulmonary hilum was clamped, after which the pulmonary vasculature of the left lung was 'washed out' with 50 ml normal saline. After weighing, the left lung was homogenized in 0·5 per cent hexadecyl trimethyl ammonium bromide (Sigma Chemical, St Louis, Missouri, USA). The supernatant was assayed spectrophotometrically for MPO activity. One unit of MPO was defined as that degrading 1 μmol peroxide per min at 25°C and calculated per g of tissue[20].

Western immunoblotting for heat shock protein 72 expression

Tissue samples from the lung, intestine and mesentery were removed, homogenized in cold phosphate buffer saline (1 ml) and centrifuged at 4100*g* for 30 min at 4°C. The supernatants were collected and protein concentration was quantified using a Coomassie protein assay reagent (Rockford, Illinois, USA). The final protein concentration of samples was diluted to 50 μg per 10 μl. The proteins were denatured at 100°C for 10 min and aliquots containing equal amounts of protein were then suspended in sodium dodecyl sulphate (SDS)–glycerol loading buffer (pH 6·8, 62·5 mmol/l Tris, 2 per cent SDS, 10 per cent glycerol, 5 per cent mercaptoethanol, 0·01 per cent bromophenol blue), and proteins were separated by SDS–polyacrylamide gel electrophoresis (ExcelGel, Pharmacia, Sweden) with 75 μg total protein loaded per lane. Proteins were then transferred to a nitrocellulose membrane (Sigma) and labelled with a primary monoclonal antibody (mbA), mouse antihuman immunoglobulin (Ig) G_1, specific for heat shock protein 72 (hsp72) (StrssGen, Victoria, British Columbia, Canada). After adding secondary mbA, sheep antimouse IgG_1 conjugated with alkaline phosphatase (Serotic, Oxford, UK), the protein was visualized using bromochloroindolyl phosphate–nitro blue tetrazolium (Sigma)[21].

Statistical analysis

All data are expressed as median (range). Kruskal–Wallis analysis of variance on ranks was used. If there was a significant difference between the groups, Student–Newman–Keuls multiple comparison procedure was applied. Statistical significance was set at $P < 0{\cdot}05$.

Results

Pulmonary microvascular leakage

Ischaemia–reperfusion resulted in a significant increase in pulmonary microvascular leakage compared with that in controls, as determined by wet:dry lung weight measurements and BAL_{prot} concentration. W:D weight ratios increased significantly from a median (range) control value of 3·72 (3·58–3·96) to an ischaemia–reperfusion value of 3·92 (3·86–4·80) ($P < 0{\cdot}05$). There was significant increase in BAL_{prot} concentration from control levels of 199·4 (135·9–280·3) μg/ml to ischaemia–reperfusion levels of 730·0 (373·5–1457·4) μg/ml ($P < 0{\cdot}05$). Thermotolerance resulted in a significant reduction in W:D ratio ((3·57) (3·33–3·70)) and in BAL_{prot} concentration (321·9 (193·2–245·1) μg/ml) compared with values in the ischaemia–reperfusion group ($P < 0{\cdot}05$).

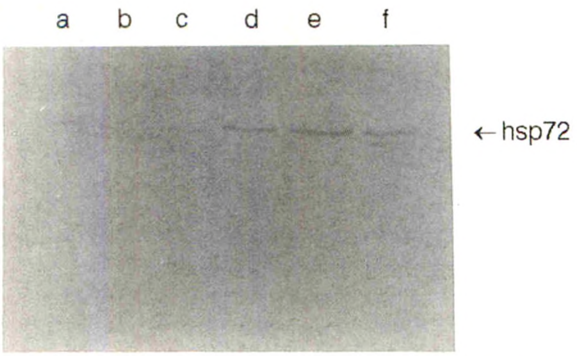

Fig. 1 Western immunoblotting for expression of heat shock protein 72 (hsp72) before ischaemia–reperfusion. Lanes d, e and f represent hsp72 in the lung, intestine and mesentery respectively in rats exposed to hyperthemia. Lanes a, b and c represent hsp72 in the lung, intestine and mesentery of rats not exposed to hyperthermia

Lung tissue neutrophil infiltration

Ischaemia–reperfusion resulted in significantly higher levels of MPO activity and BAL PMN count (3·91 (1·55–6·07) units/g and 3·5 (2·0–4·5) $\times 10^5$/ml respectively) compared with values in controls (1·25 (0·51–2·72) units/g and 0·5 (0·2–1·2) $\times 10^5$/ml respectively) ($P < 0{\cdot}05$).

In rats preconditioned with hyperthermia there was a significant reduction in MPO activity (1·89 (0·88–3·78) units/g) and in BAL PMN count (1·2 (0·2–1·5) $\times 10^5$/ml) compared with the ischaemia–reperfusion group ($P < 0{\cdot}05$).

Heat shock protein 72 expression

Fig. 1 demonstrates that hyperthermia induced expression of hsp72 in lung, mesentery and intestine. Some hsp72 activity was detected in lung tissue of non-heated animals. Previous studies in which densitometry was performed to measure the amount of hsp72 induced have also shown small amounts of hsp72 in tissues of control (non-heated) animals[11,14].

Discussion

The hypothesis was that thermal preconditioning *in vivo* might decrease lung injury secondary to lower torso ischaemia–reperfusion. This study confirmed that temporary clamping of the infrarenal aorta resulted in altered pulmonary endothelial barrier function, with oedema and increased BAL_{prot} concentration and neutrophil infiltration. Thermal preconditioning significantly decreased the lung injury. This was associated with increased expression of hsp72.

The authors and others have previously reported that aortic cross-clamping followed by reperfusion is associated with pulmonary injury and neutrophil activation[22–24]. Neutrophil activation has been implicated as one of the key mediators of distant organ damage and dysfunction caused by reperfusion injury[22,25]. The lung is particularly affected by this process. Recent studies have also confirmed the central role of the neutrophil in skeletal muscle, hepatic[26], myocardial[27] and pulmonary[22,26] injury following reperfusion. Adherence to endothelium is a prerequisite for microvascular injury. After adhering to pulmonary microvascular endothelium, neutrophils exert their toxic effects through the release of proteolytic enzymes and free radicals[22,26]. This is mediated by interaction between CD11b–CD18 adhesion glycoprotein complex expressed on neutrophils and its complementary ligand, intercellular adhesion molecule (ICAM) 1, on the endothelial cell.

Exposure of cells to a subcritical stress may protect cells and tissues from subsequent injury, possibly by inducing heat shock protein expression; this is referred to as thermotolerance. There is evidence to suggest that this phenomenon is mediated by heat shock proteins. Heat shock proteins represent a highly conserved family of constitutively expressed and stress-induced proteins. They act as molecular chaperones, playing a central role in the binding of denatured proteins[28,29]. *In vitro* studies have demonstrated that this effect is proportional to the amount of hsp72 present at the time of second injury[21,30]. *In vivo* studies have demonstrated that induction of hsp72, by heat stress, protects against ischaemia–reperfusion-induced renal, intestinal and other organ injury[14,17,31]. This study demonstrates that thermotolerance does induce expression of hsp72 in lung, mesentery and gut. Expression of the protein was associated with attenuation of ischaemia–reperfusion-induced acute lung injury.

The mechanism by which hsp72 or thermotolerance induces these changes is not clear. Thermotolerance decreases ischaemia–reperfusion-induced upregulation of ICAM-1 on the surface of renal endothelium[16]. Thermotolerance also decreases ischaemia–reperfusion-induced activation of the 5′-lipo-oxygenase pathway, decreasing synthesis of leukotriene B_4[14], which is known to induce leucocyte chemotaxis, adherence and degranulation[32]. It is possible that the protective effect of thermotolerance is through decreasing the synthesis of this molecule. There is also evidence that heat shock may enhance the cellular antioxidant defence system[33].

A hyperthermia-only group was not included in this study. This might have been useful in determining whether hyperthermia itself can lead to injury. However, previous studies have shown no significant difference in injury between animals treated with hyperthermia and controls[14,17]. The delay between induction of thermotolerance and the ischaemia–reperfusion injury was based on previous studies demonstrating that 18 h was optimal. Investigations are currently underway to establish pharmaceutical means of inducing this response over a shorter interval. As aortic aneurysm surgery is a planned procedure, preconditioning is an attractive method of reducing ischaemia–reperfusion injury. This could be particularly important in clinical practice if heat shock protein induction by pharmaceutical agents were shown to be effective in reducing the injury.

Background Adrenaline tolerance improves survival in animal models of shock. The purpose of this study was to determine the effects of adrenaline tolerance on intestinal ischaemia–reperfusion in a mouse model.

Methods Adrenaline tolerance was developed by injecting intravenous adrenaline, gradually increasing the dose to 2 mg/kg over 5 days. In experimental animals the superior mesenteric artery was clamped for 120 min and then released. Evans blue dye was given intravenously to all animals to quantify pulmonary microvascular injury. Some 60 min after clamp release, the animals were killed and the effects of reperfusion assessed on tissue samples.

Results Evans blue dye concentrations were significantly higher in animals with intestinal ischaemia–reperfusion than in those having sham intestinal ischaemia–reperfusion or in adrenaline-tolerant mice having intestinal ischaemia–reperfusion or sham ischaemia–reperfusion ($P < 0{\cdot}01$). Malonyldialdehyde levels increased significantly in the lung in the intestinal ischaemia–reperfusion group compared with those in the sham ischaemia–reperfusion group ($P < 0{\cdot}001$ for liver, lung and small intestine), whereas there was no difference in adrenaline-tolerant animals. There was no significant change induced by adrenaline tolerance in myeloperoxidase levels in any organ.

Conclusion Adrenaline tolerance reduced the lung permeability caused by intestinal ischaemia–reperfusion. Catecholamines may play a role in free radical generation induced by ischaemia–reperfusion.

The release of catecholamines during various shock states reduces mesenteric vascular perfusion. Resuscitation is accompanied by reperfusion of ischaemic bowel which is thought to cause remote organ injury, especially by neutrophil priming and release of free radicals[1]. In a series of studies it has been shown that adrenaline-tolerant dogs had improved survival from haemorrhagic, endotoxic and cardiogenic shock[2–6]. If adrenaline tolerance is indeed protective in shock states, it may also affect intestinal ischaemia–reperfusion injury by interfering with neutrophil priming or free radical formation. The purpose of this study was to investigate the effect of catecholamine tolerance on organ effects of intestinal ischaemia–reperfusion.

Materials and methods

Swiss albino mice weighing 30–35 g were studied. This experiment was performed in the laboratories of the Departments of Surgical Research and Biochemistry at Hacettepe University Faculty of Medicine. Guidelines for the use and care of laboratory animals were followed. The animals were fed with standard rodent chow and water before and after operation.

Development of adrenaline tolerance

A pilot study was performed to find the LD_{100} (lethal dose at which 100 per cent of animals die) for adrenaline. A single dose of 2 mg/kg was lethal in all of 20 animals studied. This dose was chosen as the target and a novel model for adrenaline tolerance was developed. Briefly, animals were injected with intravenous adrenaline, starting with 0·05 mg/kg which was gradually increased to 2 mg/kg over 5 days. The drug was diluted in 0·4 ml saline. Control animals were injected with an equivalent volume of saline for 5 days.

Induction of intestinal ischaemia–reperfusion

Some 72 h after completion of injections, control animals and adrenaline-tolerant mice were divided into two subgroups: intestinal ischaemia–reperfusion and sham intestinal ischaemia–reperfusion. There were between 11 and 19 animals in each subgroup. Following an overnight fast animals were anaesthetized with ketamine 60 mg/kg and xylazine 4 mg/kg. Evans blue dye (30 mg/kg) was injected intravenously. Following this, laparotomy was performed and the superior mesenteric artery (SMA) was clamped for 120 min with a microclip, followed by a 60-min reperfusion. In the sham ischaemia–reperfusion group the same procedures were performed except for SMA clamping.

Measurement of pulmonary injury

Pulmonary microvascular dysfunction was assessed by measuring the concentration of Evans blue dye within the lung. Evans blue dye binds avidly to albumin and is used as a marker of protein extravasation and inflammatory tissue injury[7,8]. After 60 min of reperfusion the animals were killed and tissues harvested. Pulmonary vessels were emptied of blood by infusing saline into the right ventricle. The lungs were then weighed, placed in 5 ml formamide and homogenized. The tissue suspension was incubated in formamide at 37°C for 16 h, after which the dye concentration was measured by spectrophotometer at 620 nm. The concentration of Evans blue dye extracted from the lungs was expressed in nanograms of dye per milligrams of wet lung weight.

Determination of reperfusion injury

After 60 min of reperfusion a portion of the right lobe of the liver, the left lung and a segment of small intestine were used for

Paper accepted 21 November 1997

analysis. Tissue malonyldialdehyde (MDA), an end-product of lipid peroxidation, was measured as a marker of free radical-induced lipid destruction. Tissue myeloperoxidase (MPO) was assessed to determine neutrophil infiltration as a marker of the severity of intestinal ischaemia–reperfusion. MPO and MDA were determined spectrophotometrically according to the methods described by Suzuki *et al.*[9] and Mihara and Uchiyama[10] respectively.

Statistical analysis

One-way analysis of variance was used to assess differences in all data followed by Newman–Keuls *post hoc* analysis. $P < 0{\cdot}05$ was considered significant.

Results

Pulmonary permeability was significantly greater in mice subjected to SMA clamping without previous induction of adrenaline tolerance (mean(s.d.) Evans blue concentration 225·9(45·5), $P < 0{\cdot}01$ *versus* other groups) (*Fig. 1*).

Mean(s.d.) MDA levels were significantly increased in lung (64·9(14·0) nmol/g), liver (57·4(8·5) nmol/g) and small intestine (83·0(15·8) nmol/g) in the intestinal ischaemia–reperfusion group *versus* sham ischaemia–reperfusion animals (46·4(10·1), 42·5(7·1) and 53·6(9·0) nmol/g respectively) ($P < 0{\cdot}001$ for all three organs). Both adrenaline-tolerant groups had significantly higher MDA levels than the sham intestinal ischaemia–reperfusion group ($P < 0{\cdot}005$ for all three organs). In addition MDA levels in the liver of both adrenaline-tolerant groups were significantly higher than in the ischaemia–reperfusion group (*Fig. 2*). There was no significant difference, however, in MDA levels between the two adrenaline-tolerant groups for all organs.

In lung tissue, mean(s.d.) MPO levels were significantly higher in the intestinal ischaemia–reperfusion group (193·2(46·6) units/g) than in the sham ischaemia–reperfusion group (114·2(52·9), $P < 0{\cdot}005$) (*Fig. 3*). Although MPO levels were also higher in liver and intestine in the intestinal ischaemia–reperfusion group, the difference was not significant in, or between, normal or adrenaline-tolerant animals.

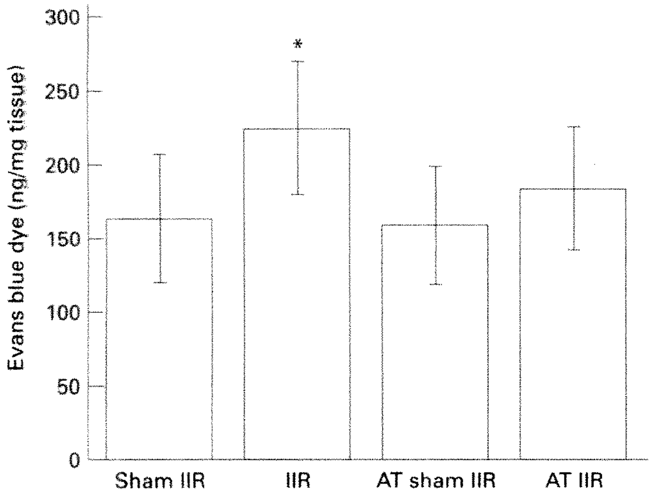

Fig. 1 Comparison of pulmonary permeability. Values are mean(s.d.). IIR, intestinal ischaemia–reperfusion; AT, adrenaline-tolerant mice. $^*P < 0{\cdot}01$ *versus* other groups (analysis of variance followed by Newman-Keuls post-hoc analysis)

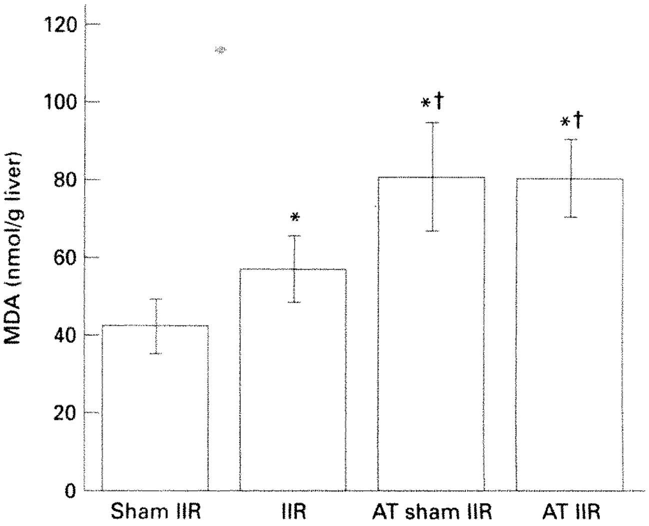

Fig. 2 Comparison of liver malonyldialdehyde (MDA) levels. Values are mean(s.d.). IIR, intestinal ischaemia–reperfusion; AT, adrenaline-tolerant mice. $^*P < 0{\cdot}001$ *versus* sham IIR; $^†P < 0{\cdot}001$ *versus* IIR (analysis of variance followed by Newman-Keuls post-hoc analysis)

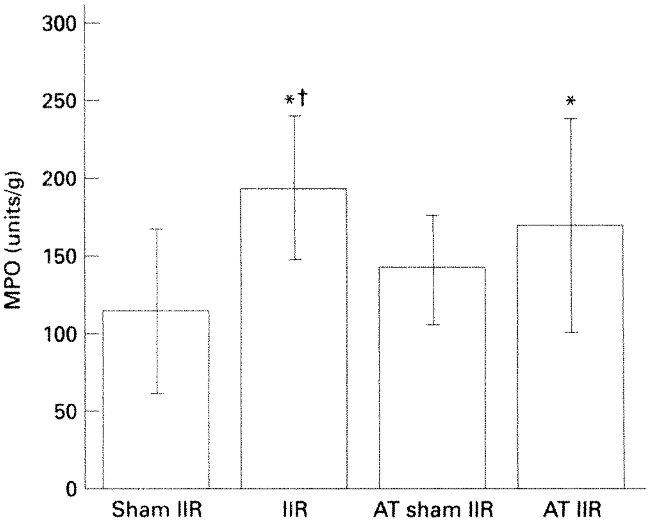

Fig. 3 Comparison of lung myeloperoxidase (MPO) levels. Values are mean(s.d.). IIR, intestinal ischaemia–reperfusion; AT, adrenaline-tolerant mice. $^*P < 0{\cdot}05$ *versus* sham IIR; $^†P < 0{\cdot}05$ *versus* AT sham IIR (analysis of variance followed by Newman-Keuls post-hoc analysis)

Discussion

Adrenaline tolerance can be produced by continued exposure to catecholamines. Various mechanisms cause this phenomenon including a decrease in the avidity of the receptors[11], a decrease in the number of receptors[11–14], an increase in the level of inhibitory G protein α-subunits[13] or a decrease in catecholamine-induced adenyl cyclase activity[12,13]. Tolerance to both α_1- and α_2-adrenergic receptor-mediated vasopressor responses in rats with transplanted phaeochromocytoma tumours can be demonstrated[15]. In patients with a phaeochromocytoma, the density of α and β adrenoceptors is decreased. This returns to normal 3 months after surgery[16].

Previous studies on adrenaline tolerance were performed on dogs. Tolerance was developed by administering intravenous adrenaline every 2–3 days for a few weeks[3]. In this study the drug was given for 5 days because gradual sclerosis of the tail skin or tail vein occurred, due to small amounts of extravasated adrenaline. The mortality rate was approximately 75 per cent by the end of 7 days. Most of the deaths occurred after the first two doses.

Ischaemia–reperfusion is associated with raised catecholamine levels caused by impairment of uptake and storage[17]. Intestinal ischaemia–reperfusion causes pulmonary vasoconstriction[18] and liver ischaemia, and is accompanied by increased catecholamine levels and pulmonary hypertension[19]. It is known that pulmonary hypertension leads to accumulation of interstitial lung water by increasing microvascular filtration pressure[20]. In the present model, decreased pulmonary permeability could be the result of an attenuated catecholamine effect.

Increased lipid peroxidation in lung, liver and small intestine in animals with intestinal ischaemia–reperfusion was evidenced by significantly increased MDA levels in all three organs. This has been demonstrated previously in different studies with significantly increased MDA levels in lung[21], and intestine[22] induced by intestinal ischaemia–reperfusion. Conversely, there was no difference in MDA levels in adrenaline-tolerant animals having intestinal ischaemia–reperfusion or sham ischaemia–reperfusion. However, MDA levels in the sham adrenaline-tolerant group were significantly higher than in the sham ischaemia-reperfusion animals. Two mechanisms might have contributed to this result. One might be ischaemic vasoconstruction and reperfusion due to the adrenaline injections, contributing to increased MDA levels. The other might be the oxidation products of adrenaline, which is known to generate free oxygen radicals[23,24].

One study[25] showed that after induction of ischaemia, inhibition of monoamine oxidase attenuates production of hydrogen peroxide, revealing the importance of catecholamine oxidation in ischaemia–reperfusion injury. In the liver, the difference between MDA levels in normal and adrenaline-tolerant animals was more evident, as both adrenaline-tolerant groups had significantly higher MDA levels than the intestinal ischaemia–reperfusion group. This might be because catecholamines are mostly metabolized in liver and monoamine oxidase has its highest concentrations in liver and kidney[26]. These findings support the hypothesis that oxidation of catecholamines leads to accumulation of oxygen free radicals.

The second result is the attenuation of intestinal ischaemia–reperfusion-induced lipid peroxidation by adrenaline tolerance. There was no significant difference between the two adrenaline-tolerant groups, showing that the intestinal ischaemia–reperfusion insult did not lead to additional lipid peroxidation. This suggests that catecholamines are involved in ischaemia–reperfusion injury, possibly having a positive modulatory role. Some reports have shown an association of catechol adrenergic agents with the xanthine oxidase system[27,28], suggesting the latter has a catalytic role for catechol adrenergic agents on xanthine oxidase. Ischaemic preconditioning might be another explanation for the protective effect of adrenaline tolerance.

MPO levels increase in lung[29,30] and intestine[22,29,30] during intestinal ischaemia–reperfusion, and act as a marker for neutrophil infiltration. In the present study, MPO levels were also increased by intestinal ischaemia–reperfusion in all three organs studied, although significantly only in the lung. In this model, adrenaline tolerance did not have any effect on intestinal ischaemia–reperfusion-induced changes in MPO levels in any organ. Catecholamines may not play a major role in neutrophil activation.

The present study indicates that catecholamines are involved in intestinal ischaemic injury and that induction of adrenaline tolerance has a possible protective role.

Background The aims of this prospective study were to analyse the health-related quality of life (QOL) changes associated with infrainguinal arterial reconstruction for chronic critical limb ischaemia (CLI) and to assess the impact of graft patency and limb salvage.

Methods Fifty-five consecutive patients, 28 women and 27 men of median age 71 (range 41–86) years, undergoing infrainguinal arterial reconstruction for CLI, consented to participate in the study. QOL was assessed using the Short Form 36 (SF36) health survey questionnaire, which was completed before and at 1, 3, 6 and 12 months following surgery. Graft patency was assessed by duplex imaging at the same postoperative intervals.

Results CLI severely impaired QOL. Cumulative graft patency at 1, 3, 6 and 12 months after surgery was 82, 78, 76 and 64 per cent respectively. Reconstruction resulted in significant improvements in the SF36 domains Physical Functioning, Pain, Vitality and Social Functioning ($P < 0{\cdot}01$). With a patent graft these improvements began soon after surgery and were maintained for the 12 months studied. Following irredeemable graft occlusion, patients who had secondary amputation also described some QOL improvements.

Conclusion A patent graft following infrainguinal arterial reconstruction for critical ischaemia results in an immediate and lasting improvement in health-related QOL.

The incidence of chronic critical limb ischaemia (CLI) is estimated at 50–100 per 100 000 population per year[1]. Reconstructive arterial surgery is increasing[2–4]. Compared with amputees, patients who undergo revascularization are less likely to die or need long-term institutional care, are more likely to have a short hospital stay, to be discharged home and to survive longer once discharged[4–6]. Successful revascularization is more cost effective than amputation[7]. Despite these advantages there is little information available concerning the impact of vascular reconstruction on the quality of life (QOL). Previously, domain-specific questionnaires have been used which make comparisons difficult and no information is given regarding QOL before intervention. Conclusions regarding QOL benefits following vascular reconstruction are difficult to make[8,9]. Early postoperative QOL assessment is essential to ensure that the impact of postoperative recovery and complications is not overlooked[10,11]. The mortality rate of patients with chronic critical ischaemia is 10–20 per cent per annum; it is therefore important that the functional outcome of patients who die in the early postoperative period is documented as fully as possible. Sequential postoperative assessments are preferable in order to identify trends in QOL[12]. The aim of this prospective observational study was to analyse the impact of infrainguinal arterial reconstruction for critical ischaemia on patient-reported QOL and to assess the effect of graft patency and limb salvage.

Patients and methods

Over 6 months, 65 consecutive patients with CLI according to International Society for Cardiovascular Surgery (ISCVS) criteria[13], listed for infrainguinal arterial reconstruction, were invited to participate in the study. Fifty-five patients consented and were studied prospectively. Graft patency was assessed at 1, 3, 6 and 12 months following surgery by duplex imaging.

Patients' QOL was assessed using the Short Form 36 (SF36) before and at 1, 3, 6 and 12 months after surgery. The SF36 was developed from the Medical Outcomes Study questionnaire in the USA. In this study the UK version was used. The SF36 contains 36 items which measure eight QOL dimensions or domains: Physical Functioning, Role limitation due to Physical problems (Role Physical), Social Functioning, Role limitations due to Emotional problems (Role Emotional), Mental Health, Vitality, Pain and General Health. Item scores for each domain are coded, summed and transformed on to a scale from 0 (worst possible score) to 100 (best possible score). The SF36 is the product of a vast amount of developmental work and psychometric testing in the USA[14–18].

Data were collected on a Microsoft Access database and analysed using a Microsoft (Wokingham, UK) Excel spreadsheet with Astute (University of Leeds, UK) Statistical Analysis software. QOL scores were not normally distributed (Kolmogorov–Smirnov goodness of fit test). QOL scores for the whole group are presented as median values and Kruskal–Wallis one-way analysis of variance was used to assess significant changes.

Subgroup QOL analysis, based on graft patency, is presented as effect sizes, and in this case the Mann–Whitney U test was used for comparison with pretreatment values. Effect sizes were calculated by dividing the difference between the pretreatment and post-treatment median values by the interquartile range of the pretreatment values[19].

Subgroup QOL analysis 12 months after intervention, based on graft patency and limb salvage, is presented as standard scores.

Paper accepted 14 December 1997

Only at 12 months did each subgroup contain sufficient patients for meaningful comparison. Standard scores were calculated by dividing the differences between the median scores of each subgroup and those of the general population by the interquartile range of the general population[20,21].

Results

The 55 patients studied, 28 women and 27 men of median age 71 (range 41–86) years, reported a median symptom duration of 12 months (range 2 months to 30 years). The incidence of co-morbidity and predisposing factors according to reporting standards recommended by the ISCVS is shown in *Table 1*[13]. Previous ipsilateral interventions included 15 infrainguinal bypass procedures, three superficial femoral artery percutaneous transluminal angioplasties (PTAs) and five suprainguinal inflow procedures. Previous contralateral interventions included six infrainguinal bypass procedures, one superficial femoral artery PTA and four amputations. Nineteen patients had rest pain and 36 had tissue necrosis. Nineteen patients underwent a femoropopliteal (six above knee, 13 below knee) bypass graft, 33 a femorocrural (13 anterior tibial, ten posterior tibial, ten peroneal) bypass graft and three a femorodorsalis pedis graft. Long saphenous vein (LSV) alone was used in 22 patients (five *in situ*, 17 reversed grafts), a combination of LSV and arm vein in eight, externally supported polytetrafluoroethylene (PTFE) with vein cuff in 20, and composite PTFE and vein graft in five.

The ten patients, seven men and three women, who declined to participate were significantly older than those in the study group (median age 75 (range 71–90) years) ($P = 0{\cdot}01$, Mann–Whitney U test), but were otherwise similar to the study group in terms of sex, co-morbidity, factors predisposing to peripheral vascular disease, severity of lower limb ischaemia, previous ipsilateral or contralateral interventions, and QOL before intervention. Cumulative graft patency was 82, 78, 76 and 64 per cent at 1, 3, 6 and 12 months after surgery respectively[13] (*Table 2*). Four of the 11 patients who had secondary amputation were completely wheelchair-dependent at 12 months.

Infrainguinal arterial reconstruction significantly improved SF36-measured Physical Functioning, Pain, Vitality and Social Functioning scores (*Fig. 1*). There were no significant improvements in the SF36 domains of Role Physical, General Health, Role Emotional or Mental Health following reconstruction. Subgroup analysis according to graft patency (*Fig. 2*) demonstrated that a patent graft results in an immediate improvement in Physical Functioning, Role Physical, Pain and Social Functioning, which are maintained for up to 12 months. A delayed improvement in Vitality was observed in patients with a patent graft at 6 and 12 months. The only QOL domains that improved following graft occlusion were Pain, Vitality and Social Functioning at 6 months. No significant improvements in Physical Functioning and Role Physical were detected at any of the follow-up assessments if graft occlusion had occurred (*Fig. 2*). Graft patency had no influence on General Health, Role Emotional or Mental Health dimensions.

Subgroup QOL analysis based on graft patency and limb salvage at 12 months after intervention (*Fig. 3*) demonstrated that patients with a patent graft were the only subgroup to gain any benefit in the SF36 domains of Physical Functioning and Role Physical, but did not quite attain the values of a matched normal population (standard score below zero). Patients with an occluded graft, irrespective of whether amputation was needed, had little or no change from pretreatment scores in these two domains at 12 months, with scores inferior to a matched population (standard score less than − 1). Patients with a patent graft and those who required secondary amputation had similar improvements in the domains of

Pain, Vitality, Mental Health and Social Functioning, with standard scores in the first three domains approaching those of a matched population. In several of the psychological domains (e.g. General Health, Vitality, Role Emotional and Mental Health) the standard scores for secondary amputees were superior to those in patients with a patent graft. Patients with a non-redeemable occluded graft who declined amputation, although few in number, seemed to return to the dismal QOL experienced before intervention, and demonstrated further deterioration in many of the psychological domains. This group of patients had the lowest QOL score in virtually all of the SF36 domains, with scores falling way below those of a matched population (standard score less than − 1·5).

Discussion

A 12-month cumulative patency rate of 64 per cent concurs with previous studies, given that 27 per cent of procedures were secondary, sufficient LSV was available in only 40 per cent of patients and 65 per cent had tissue necrosis before surgery[22]. A 1-year mortality rate and overall loss to follow-up, including these deaths, of 13 and 22 per cent respectively matches other studies[23,24]. This relatively large loss remains a major problem when studying patients with CLI and is one of the weaknesses of this study. Frequent sequential assessments were done to try to avoid the omission of QOL data in potentially the sickest patients; however, these are the patients often lost to follow-up and the SF36 results are biased by their omission.

The SF36 is the most appropriate generic health-related QOL assessment for use in patients with CLI[18,25]. Other studies have demonstrated QOL improvements with other instruments[26,27]. CLI has a profoundly detrimental effect on health-related QOL when compared with age-matched population norms[16,20] and other common clinical conditions encountered in the National Health Service[21].

This study demonstrated that successful reconstruction results in almost immediate QOL improvements. However, it can take time to recover fully from surgery, with patients with patent grafts demonstrating continuing improvements in several QOL domains (e.g. Physical Functioning) for up to 12 months following surgery. Significant improvements in some domains (e.g. Vitality) were not evident until 6 months after surgery. Early measurement of QOL is essential and patients should be encouraged to continue to attend for further follow-up. A patent graft has a profound, immediate and lasting impact on QOL which justifies the time and expense associated with these procedures and in the maintenance of graft patency. Although the number of patients with a non-salvageable failed graft is small, this study indicates that a secondary amputation results in severe and lasting limitations to physical activities despite relatively good rehabilitation rates, but improves pain and many of the psychological QOL domains. Potential explanations for the psychological benefits demonstrated in amputees at 12 months may include relief from the ongoing problems of recurrent limb ischaemia and the realization that the daunting problem of life as an amputee can be addressed and overcome. The severe QOL impairment in patients with a failed graft who do not accept amputation may be expected as they not only suffer recurrent CLI but have undergone major surgery in vain.

This study supplies evidence to support an aggressive approach to surgical reconstruction in patients with CLI. Following surgery QOL improvements are observed as long as the graft remains patent. Secondary amputation following non-redeemable graft occlusion also seems to have some QOL benefits.

Ward *versus* intensive care management of high-risk surgical patients

J. E. CURRAN and R. M. GROUNDS

Anaesthetic Department, St George's Hospital, Blackshaw Road, London SW17 0QT, UK
Correspondence to: Dr R. M. Grounds

Background Selection of high-risk surgical patients for preoperative and perioperative admission to an intensive therapy unit (ITU) for enhancement of oxygen delivery may reduce postoperative morbidity and mortality rates. Limited resources may prevent admission of all suitable patients. This audit study examined whether it is possible to select patients most at risk and thus reduce surgical morbidity and mortality rates when ITU services are limited.

Methods This was a retrospective audit comparing the actual outcomes of complications and death with predicted outcomes using the POSSUM socre (Physiological and Operative Severity Score for the enUmeration of Mortality and morbidity) for 101 general surgical and vascular patients who would have fulfilled previously suggested criteria for preoperative admission to the ITU. Main outcome measures were the number of preoperative ITU admission criteria, American Society of Anesthesiologists (ASA) and POSSUM scores, preoperative oxygen delivery values, intravenous fluid therapy, length of ITU stay, length of hospital stay, postoperative complications and 28-day mortality.

Results Medical staff allocated patients appropriately. There was a lower mortality rate than predicted from individual POSSUM scores. Patients who were admitted to the ITU before operation had the highest ASA scores, admission criteria and POSSUM scores; they also had significantly lower mortality and morbidity rates than predicted by the POSSUM scoring system.

Conclusion Patients with the greatest reduction in mortality and morbidity rates were admitted to the ITU before operation and had cardiovascular physiology 'optimized' before surgery.

Goal-oriented haemodynamic therapy may reduce mortality in patients at high perioperative risk[1–8]. In 1992 this institution introduced a goal-directed protocol for perioperative enhancement of oxygen delivery for patients at high risk of complications and death after various surgical procedures. This followed a randomized prospective study[1] that had shown a clear benefit of perioperative enhancement of oxygen delivery of patients to the indices suggested by Shoemaker *et al.*[7]. The protocol required admission of all patients expected to be at high postoperative risk to the intensive therapy unit (ITU) before operation (*Table 1*). In the ITU these patients had cardiovascular physiology enhanced by means of specific treatment guidelines suggested by Shoemaker *et al.*[7] and Boyd *et al.*[1]. When the defined treatment goals had been achieved, the patients went to theatre for surgery, returning to the ITU afterwards.

A retrospective study of a 3-month period was conducted, 2 years after the introduction of goal-oriented perioperative enhancement. Owing to lack of ITU beds not all the patients who fulfilled one or more of the criteria for preoperative ITU admission were able to be treated in this fashion.

The purpose of this study was to answer the following three questions. Were medical staff selecting the most appropriate patients for the limited ITU facilities? When patients had been selected for perioperative oxygen enhancement, were they being treated appropriately and correctly? Does ITU management improve the outcome measures of morbidity and mortality in these patients when compared with a previously documented and established database of similarly ill patients?

Patients and methods

Hospital theatre records were reviewed and a list was compile of all general surgical and vascular patients who had had a operation lasting longer than 90 min or who were over 70 year old and having a major operative procedure during a 3-mont winter period from December to February. All patient note were reviewed to determine whether they fulfilled the criteria fo perioperative enhancement of oxygen delivery (*Table 1*). If the

Table 1 Shoemaker–Boyd entry criteria*

Any patient whose operation is planned to exceed 90 min and who has one or more of the following:

1. Previous severe cardiorespiratory illness with current reduced cardiorespiratory reserve (e.g. acute myocardial infarction, chronic obstructive pulmonary disease, cerebrovascular accident)
2. Respiratory failure (P_{aO_2} less than 6 kPa or F_{iO_2} greater than 0·4 or currently requiring mechanical ventilation)
3. Shock (mean arterial pressure less than 60 mmHg, central venous pressure lower than 15 mmHg, urine output less than 20 ml h^{-1}, cold and clammy)
4. Acute abdominal catastrophe with haemodynamic instability
5. Massive blood loss (more than 8 units)
6. Age over 70 years *and* evidence of significantly reduced physiological reserve in one or more organs
7. Acute renal failure (urea greater than 20 mmol l^{-1}, creatinine greater than 260 mmol l^{-1}) of sudden recent onset
8. Planned extensive ablative surgery for carcinoma (e.g. gastrectomy, oesophagectomy)
9. Late-stage vascular disease associated with aortic disease

*Criteria suggesting that a patient may benefit from admission to an intensive therapy unit before operation for cardiovascular augmentation and pharmacological enhancement of physiology to achieve a tissue oxygen delivery of at least 600 ml min^{-1} m^{-2} body surface area before surgery[1,7]. P_{aO_2}, arterial partial pressure of oxygen; F_{iO_2}, fraction of inspired oxygen

Paper accepted 18 November 1997

did, they were included in the audit. The outcome of these patients following operation was analysed retrospectively. Actual outcome was compared against predicted outcome using a surgical scoring system to evaluate the severity of illness for individual patients and to compare the outcome of individual patients against an established database of similar patients in other hospitals in the UK. This scoring system, the Physiological and Operative Severity Score for the enUmeration of Mortality and morbidity (POSSUM), devised by Copeland *et al.*[9], has been well evaluated for surgical audit and allows a predicted morbidity and mortality risk to be calculated for each patient. POSSUM has been used for general and vascular surgery audit[10,11]. It has been shown to give a better prediction of outcome for surgical patients than Acute Physiology And Chronic Health Evaluation (APACHE) II[12] (a scoring system for recording both acute physiological status and chronic health changes in the first 24 h after admission to an ITU).

Patients who fulfilled the criteria were separated into three groups based on the time of admission to the ITU: (1) no admission to the ITU, (2) admission to the ITU after operation, and (3) admission to the ITU before operation. The following data were collected: type of operation carried out, age, weight, all perioperative indices of cardiovascular performance, perioperative fluids, postoperative complications or death within 28 days of operation, length of ITU stay, duration of hospital stay, and American Society of Anesthesiologists (ASA) and POSSUM scores.

The ASA score[13] is a five-point assessment of preoperative physical status devised to classify patients into grades according to their preoperative general medical condition. POSSUM takes into account the following patient-derived data: age, cardiac signs, chest radiograph, respiratory history, blood pressure, heart rate, Glasgow Coma Score, haemoglobin level, white cell count, plasma urea, sodium and potassium concentrations, and the electrocardiogram. Each item in the score is graded and the patient is awarded 1, 2, 4 or 8 points for increasing derangement. The minimum score is 12 and the maximum 120. Scoring is carried out immediately before operation but after resuscitation has taken place, thus avoiding the complication of lead-time bias[14,15]. Included in POSSUM is the Operative Severity Score (OSS), which is taken after (and is dependent on) the surgical procedure performed[9]. Using POSSUM it is possible to predict morbidity and mortality risk for a particular patient based on the outcome of similar patients in the POSSUM database. Prediction of morbidity and mortality was made for the patients in this audit and compared against actual outcome.

Furthermore, to attempt to identify whether there were specific groups of patients who might be either at risk from treatment or potentially able to benefit from it, three groups were subdivided into patients with a predicted morbidity or mortality rate of 50 per cent or less ('low risk') and those with a predicted morbidity or mortality rate of 51 per cent or more ('high risk').

Patients admitted to the ITU before operation were treated according to established protocols based on a previous study[1] of perioperative oxygen enhancement. Initial treatment involved supplemental oxygen (where appropriate), intravenous fluids and/or intravenous blood products if required. The immediate aims were to achieve arterial oxygen saturation of over 94 per cent, pulmonary arterial occlusion pressure of between 12 and 14 mmHg, haemoglobin concentration greater than $12\ \mathrm{g\ dl^{-1}}$, mean arterial pressure of 80–110 mmHg and urine output of over $0{\cdot}5\ \mathrm{ml\ kg^{-1}\ h^{-1}}$. After this initial treatment the cardiac index was measured and oxygen delivery index (DO_2I) was calculated. If this was less than $600\ \mathrm{ml\ min^{-1}\ m^{-2}}$ body surface area, an intravenous inotrope or vasodilator was commenced. The dose was doubled every 30 min until a DO_2I of $600\ \mathrm{ml\ min^{-1}\ m^{-2}}$ was achieved or side-effects were noted. The endpoint of a DO_2I of $600\ \mathrm{ml\ min^{-1}\ m^{-2}}$ for inotrope and/or vasodilator therapy was chosen because this was the median value noted for survivors by Bland *et al.*[2].

Postoperative complications were recorded retrospectively and were defined as in Boyd *et al.*[1] by specific diagnostic criteria.

Statistical analysis

Data are presented as mean(s.e.m.) or median, and were compared with a paired t test, the Mann–Whitney U test or Fisher's exact test as appropriate using the GraphPad Prism (v2.0) program for Apple Macintosh (GraphPad Software, San Diego, California, USA). A significant difference was assumed if $P < 0{\cdot}05$.

Results

In all, 129 patients' notes were reviewed. Of these, 28 patients did not fulfil the criteria required for preoperative admission to the ITU and their notes were not studied further. Some 101 patients fulfilled the entry criteria for perioperative intensive care and goal-oriented haemodynamic therapy. Of these, 40 (40 per cent) went to the ITU before operation, 31 (31 per cent) went to the ITU after operation, and 30 (30 per cent) did not go the ITU at all. The case mix for all three groups was two-thirds general surgical and one-third vascular surgery. The age of the patients was similar in all three groups (*Table 2*).

It can be seen that the number of Shoemaker–Boyd criteria[1,7] used for entry to this study increased between the three groups. Patients not admitted to the ITU had the lowest mean number of criteria, and those with the greatest mean number were admitted to the ITU before operation. Patients who were admitted to the ITU after

ITU, intensive therapy unit; ASA, American Society of Anesthesiologists; POSSUM, Physiological and Operative Severity Score for the enUmeration of Mortality and morbidity; OSS, Operative Severity Score. *$P = 0{\cdot}011$, ‡$P = 0{\cdot}0019$, #$P = 0{\cdot}0015$ (ITU after *versus* ITU before operation); †$P < 0{\cdot}0001$, **$P < 0{\cdot}0005$ (ITU before operation *versus* no ITU); §$P = 0{\cdot}027$, ¶$P = 0{\cdot}001$ (ITU after operation *versus* no ITU) (Mann–Whitney U test) operation had an intermediate number of criteria. Likewise, there was an increase in ASA and POSSUM scores between patients not going to the ITU before operation (*Table 2*). These differences were significant. However, there was no significant difference in OSS (representing the complexity of the operation) between groups going to the ITU, although the group of patients who did not go to the ITU had less complex operations as scored by the OSS. The proportion of cases admitted as emergencies was highest in the group that went to the ITU before operation.

Table 3 shows duration of ITU and hospital stay as well as the volume of intravenous fluid given before operation and that given during the 24 h from the start of operation. Median duration of ITU stay was nearly twice as long in those who were admitted to the ITU before operation compared with those who were admitted only once the operation had been performed. However, it can be seen from the range of ITU stay that postoperative stay was very variable. Although the time spent in the ITU includes time before operation, it does not include operating time. However, it is difficult to determine the actual time taken for preoperative enhancement because some elective patients were admitted the evening before operation and remained in the ITU overnight even though physiological cardiovascular enhancement may have taken place several hours earlier. In view of this and the very wide range of ITU stay it was not deemed appropriate to apply any form of statistical testing to the data on ITU stay. After operation, the length of hospital stay did not alter significantly between the groups. Patients with prolonged postoperative hospital stay were confined to the two groups admitted to the ITU either before or after operation.

ITU, intensive therapy unit

Preoperative fluid management also differed between the groups, with the group that went to ITU before operation receiving most. Both other groups received intravenous fluids before operation, those going to the ITU after surgery receiving the greatest amount. However, it can be seen that intravenous fluid given to all three groups in the perioperative 24 h was similar, with patients going to the ITU after operation receiving slightly more than those in the other two groups. Despite the large amount of intravenous fluid administered during this perioperative phase (more than 20 litres in some cases) there was no recorded case of cardiac failure or pulmonary oedema as a consequence of intravenous fluid overload. It should be noted that all patients who were admitted to the ITU (both before and after operation) had intravascular fluid status monitored with a pulmonary artery flotation catheter.

The OSS for the two groups of patients admitted to the ITU was similar. The numbers of recorded complications rose in parallel with the numbers of admission criteria, ASA and POSSUM scores. Patients who were not admitted to the ITU had a lower number of complications, with only 13 of 30 being recorded as having defined postoperative complications, than the sicker patients with the higher POSSUM scores who went to the ITU both before and after operation. Patients who were admitted to the ITU after surgery had the largest number of complications (26 of 31 patients) despite being significantly fitter physiologically before operation than those who went to the ITU before operation.

Mortality at 28 days after operation reflects the increasing illness and operative complexity of the three groups: only two of 30 patients who did not go to the ITU had died, compared with seven of 31, of those who went to the ITU after operation and 12 of 40 who went to the ITU before operation.

Using POSSUM and OSS for these patients, a comparison could be made between the three groups for predicted and actual 28-day mortality and morbidity rates. The POSSUM-predicted mortality rate was 19 per cent for patients who did not go to the ITU, 37 per cent for those who went to the ITU after operation and 57 per cent for those who went to the ITU before operation. The actual mortality rates were consistently lower (*Table 4*). In the group who went to the ITU before operation the

Table 4 Actual and predicted 28-day mortality and morbidity rates grouped by timing of admission to the intensive care unit

	No ITU ($n = 30$)	ITU after operation ($n = 31$)	ITU before operation ($n = 40$)
Mortality rate (%)			
Actual*	7	23	30‡
Predicted	19	37	57
Morbidity rate (%)			
Actual†	67	84	70§
Predicted	58	75	90

*Actual no. of patients alive at 28 days was 28, 24 and 28 respectively for no intensive therapy unit (ITU) admission, ITU after operation and ITU before operation; †actual no. of patients with postoperative complications was 20, 26 and 28 respectively. ‡$P = 0{\cdot}024$, §$P = 0{\cdot}048$ (actual *versus* predicted value, Fisher's exact test) reduction in mortality rate from that predicted was significant ($P = 0{\cdot}024$).

Similarly the complication rate seen in the patients admitted to the ITU before operation was lower than that expected (72 *versus* 90 per cent, $P = 0{\cdot}048$). However, for patients admitted to the ITU after operation or not admitted to the ITU at all, there was a slightly higher complication rate than that predicted (*Table 4*).

To determine which patients obtained benefit from the ITU each of the three groups was divided into two subgroups, 'high' and 'low' risk, based on the POSSUM-predicted outcome. In the high risk groups (51–100 per cent predicted risk) there was a significant reduction in mortality rate in patients who were admitted to the ITU before operation (*Table 5*). The POSSUM-predicted mortality rate for this group was 77 per cent but the actual mortality rate was only 32 per cent. In the groups predicted to have a greater than 50 per cent likelihood of postoperative complications, only patients admitted to the ITU before operation had fewer complications than predicted.

In the subgroups designated as at 'low risk' (i.e. less than 50 per cent risk of death or complications) there was no significant difference between predicted and actual outcome. The predicted mortality rate in the low-risk patients having preoperative care was 28 per cent, but four of 15 (27 per cent) patients actually died.

Table 6 shows the features of 40 patients who were admitted to ITU before operation. These patients have been divided into two groups depending on whether or not they achieved the target of tissue oxygen delivery of equal to or greater than 600 ml kg^{-1} mg^{-2} body surface area.

Fourteen patients achieved a tissue oxygen delivery of equal to or greater than 600 ml kg^{-1} m^{-2} body surface area before being transferred to the operating theatre. The other 26 patients did not achieve this goal. These latter patients had a slightly higher POSSUM but slightly lower OSS. The group of patients who did not achieve a DO_2I greater than 600 ml kg^{-1} m^{-2} were older and included a slightly greater proportion of emergency patients. In effect this group was older and more frail, with less cardiovascular and respiratory reserve.

Both groups of patients had a resting DO_2I of less than 600 ml kg^{-1} m^{-2} and in both there was an increased DO_2I before operation. Neither group showed any significant increase in heart rate before operation and the median volume of intravenous fluid given to both groups before surgery was similar. The postoperative ITU stay of the two groups was the same but there was a large range. Postoperative hospital stay was shorter in patients who did not achieve a DO_2I greater than 600 ml kg^{-1} m^{-2} but the range in both groups was very wide. The postoperative complication rate in the two groups was similar at 64 and

65 per cent for those who acheived or failed to achieve the target DO_2I respectively, and was lower, although not significantly so, than the POSSUM-predicted morbidity rate of 93 and 89 per cent respectively.

The mortality rate for both groups was lower than the POSSUM-predicted mortality rate. Although the mortality rate was more than halved in one group and nearly halved in the other from that predicted, this improvement was not statistically significant.

Discussion

A policy of perioperative enhancement of oxygen delivery was introduced in 1992 for surgical patients at high risk of significant postoperative morbidity and mortality. This uncommon but aggressive perioperative multidisciplinary policy was introduced following a study carried out at this hospital which had shown a 75 per cent reduction in mortality rate and a halving of the mean number of complications per patient[1].

As a result of an excess of emergency admissions over available ITU beds during the winter of 1994–1995 it was impossible to adhere to the previous policy of admitting to the ITU before operation all patients who fulfilled the criteria for perioperative enhancement of oxygen delivery. Consequently it was possible to conduct a retrospective audit to compare outcome for patients on the general surgical ward *versus* two types of ITU care. This study examined whether this forced rationing affected outcome while still allocating the greater proportion of resources to the most ill.

Shoemaker *et al.*[7] in 1988 showed that patients requiring major surgery and who also had pre-existing physiological impairment of one or more major organ systems were at major risk of perioperative complications and death. They also suggested that if this group of patients had cardiovascular and respiratory physiology deliberately enhanced above the median values of known survivors to achieve tissue oxygen delivery of 600 ml min^{-1} m^{-2}, then complication and mortality rates could be reduced. This work was subsequently confirmed in patients with hip fractures[16], peripheral vascular surgery[6], severe trauma[4], and general and vascular surgery[1]. More recently, however, a number of studies has suggested that this aggressive form of intervention is of dubious value[17–20]. The common feature of these later studies is that enhancement of cardiovascular physiology was applied after the patient had developed complications and was already showing signs of early organ failure. Bone *et al.*[20] studied patients only after they had already developed respiratory failure and adult respiratory distress syndrome. Hayes *et al.*[18] studied patients who were critically ill in the ITU. Many of their patients were medical patients who had not had any form of surgery. Gattinoni *et al.*[17] studied patients who had already failed to respond to conventional ITU therapy for at least 24 h before entry to the study. It would appear that this technique is of greatest benefit if instituted before surgery and maintained throughout the procedure and into the immediate postoperative period.

This audit sought to determine whether the therapy could be selectively and appropriately applied to a high-risk group of patients at a time when resources were limited. Could junior resident surgical, ITU and anaesthesia staff selectively ration resources? Results show that patients who fulfilled the criteria for entry but did not come to intensive care had a lower number of criteria and lower POSSUM and ASA scores. Using three different methods (Shoemaker criteria, ASA score or POSSUM) of assessing the patients for ITU or non-ITU treatment, the medical staff were selecting patients for preoperative or postoperative ITU care, or indeed no ITU care, very appropriately. It is impossible to ascertain retrospectively whether the selection of patients for treatment was based on scientific method (i.e. use of one of the three scores), whether they simply allocated the patients to the three different treatment groups according to their clinical impression of the severity of illness, or whether allocation depended merely on the availability of ITU beds. However, the allocation of resources seems to have been appropriate.

In answer to the second question of whether patients admitted to the ITU before operation were treated according to the protocol, only 14 of 40 patients achieved tissue oxygen delivery as high as that suggested by Shoemaker *et al.*[7]. However, despite not achieving the aims of the goal-oriented therapy, outcome was improved when these patients were compared with a previously documented database of similar patients treated in other hospitals.

Outcome was better than would have been predicted from the POSSUM score in patients who were admitted to the ITU before operation and subjected to physiological enhancement of cardiovascular and respiratory systems. It could reasonably be argued that this improvement was merely the product of the increased experienced, expertise and resources available to patients being treated in a teaching hospital. However, if this were the case, an improvement would have been expected in all patient treatment groups; this did not occur. The POSSUM database represents the outcome after surgery at a number of other hospitals in the UK, both teaching and district general hospitals. It seems that patients who went to the ITU before operation gained some advantage compared with a large reference series from a range of general and teaching hospitals.

Despite the improved outcome in patients admitted to the ITU before operation, treatment protocol goals were not achieved in 65 per cent of those sent to the ITU before operation. This may explain why the results obtained were not as good as those seen in the original controlled clinical study[1]. It was clear from the patient notes that one of the major reasons for not achieving the target of tissue oxygen delivery was impatience amongst medical and theatre staff, particularly surgical staff, to proceed to operation. This reaction is understandable, but the purpose of audit is to identify areas of practice where outcome may be improved. This audit suggests that ITU staff should be more vigorous in defence of their position in not letting patients go to theatre before they are properly prepared. However, this shift must not encourage delay in taking patients to theatre where further delay would be life threatening. Such decisions represent a difficult balance and should be taken in consultation with senior ITU, anaesthetic and surgical staff.

It would seem from this study that the preoperative physiological state of the patient is the most important factor determining outcome following major surgery. The three recorded indices of reduced physiological reserve – ASA status, POSSUM and number of Shoemaker criteria – were significantly different between the three groups of patients but OSS was almost the same. The less ill patients were being subjected to the same sort of operative intervention but their morbidity and mortality rates were considerably lower. Furthermore, although the OSS for groups of patients admitted to the ITU either before or after operation was similar, the POSSUM and ASA score were both higher in the group admitted to the ITU before operation; despite this, patients admitted to the ITU before operation had fewer postoperative complications.

Artificially dividing the three groups into 'high' and 'low' risk groups has possibly identified patients who may benefit most from this sort of multidisciplinary aggressive approach to surgery. The biggest improvement in both mortality and complication rates was in patients with the highest prediction of postoperative problems and who were admitted to the ITU before operation. The report of the National Confidential Enquiry into Perioperative Deaths[21] suggested that a common cause of postoperative death was overvigorous use of intravenous fluids causing heart failure and death. This audit does not support this view. It can be seen that some patients received as much as 22 litres of intravenous fluids over the 24 h surrounding the operation. Despite this, no patient developed heart failure due to fluid overload during the perioperative period. The authors consider that this may be due to careful monitoring of the cardiovascular status of patients and enthusiasm for the use of pulmonary artery catheters to achieve this.

This study has shown that it is possible to select patients who most require ITU care. It is clear that not all patients who fulfil the Shoemaker–Boyd criteria need intensive care before operation. Following this audit, the authors have changed the criteria for patients who require preoperative ITU 'optimization'. They now suggest that the criterion for preoperative admission and perioperative enhancement should be 'a patient whose operation is planned to exceed 90 min and who has two or more of the criteria shown in *Table 1*'.

Soave's procedure: the final sphincter-saving solution for iatrogenic rectal lesions

J. L. FAUCHERON, R. ROSSO, E. TIRET, E. KELI, K. P. NUGENT, P. FRILEUX and R. PARC

Department of Alimentary Tract Surgery, Hôpital Saint Antoine, 184 Rue du Faubourg Saint-Antoine, 75 012 Paris, France
Correspondence to: Professor R. Parc

Background Restoring intestinal continuity in the presence of radiation-induced rectal lesions and following low colorectal anastomotic complications or low Hartmann's procedure may be fraught with difficulties. Soave's procedure avoids potentially hazardous perirectal dissection. This study examined the morbidity and mortality as well as functional results.

Methods Between January 1978 and July 1994 30 consecutive patients underwent Soave's operation as a final attempt to restore coloanal continuity. The pathology was radiation-induced lesions in 15 patients, low colorectal anastomotic complications in nine and low Hartmann's reconstruction in six.

Results Mean length of follow-up was 4·2 (range 1–16) years. There was no operative mortality. Early complications included one patient with postoperative haemorrhage, one with small bowel obstruction and four with pelvic or perineal sepsis. Late complications included four incisional hernias, three anastomotic strictures which were treated by dilatation, and one recurrent ischaemic colitis. Continence was normal in 19 of 23 evaluable patients.

Conclusion Soave's procedure obviates the need for extensive pelvic dissection, providing good technical and functional results in both the long and short term.

In certain rectal conditions such as radiation-induced lesions, stenosis with or without fistula following the disruption of a low colorectal anastomosis and reversal of a low Hartmann's procedure, there may be retraction of the pelvic tissues and abundant pelvic fibrosis. Rectal dissection under these conditions may be hazardous and even dangerous; risks include haemorrhage and injury to the pelvic nerves and neighbouring organs such as the vagina, ureters and iliac vessels. Under these circumstances, Soave's operation, which consists of a transrectal coloanal sleeve anastomosis without the need for perirectal dissection, may provide the final opportunity to restore continuity, the alternative being definitive colostomy.

Soave's operation was originally described in 1964 for the treatment of Hirschsprung's disease[1] and is still used by a few authors for this indication[2,3]. In 1972, Parks described a similar operation for the treatment of benign rectal conditions in adults[4], and some surgeons advocate this operation in severely constipated young patients to avoid pelvic nerve injury[5,6].

This study examined the technical and functional results of Soave's operation for patients with iatrogenically induced rectal lesions in whom colostomy was being considered or had already been constructed.

Patients and methods

Thirty consecutive patients underwent Soave's operation between January 1978 and July 1994 for the following rectal conditions: radiation-induced lesions ($n = 15$), low colorectal anastomotic complications ($n = 9$) and low Hartmann's reconstruction ($n = 6$). Case records for all patients were reviewed retrospectively. In addition 25 patients were interviewed in late 1995.

There were ten men and 20 women of mean age 54 (range 23–82) years. Twenty-eight patients had had one or more previous rectal resections and 15 had had a previous colectomy. Twenty-one patients had a history of pelvic sepsis, of whom 18 had a rectal fistula at the time of surgery, and 24 already had a colostomy. Twenty-eight patients had severe pelvic fibrosis. The mean time interval from complication to Soave's procedure was 19 (range 1–79) months. Where the initial diagnosis had been malignancy, the procedure was performed only after examination and investigations had proved there was no pelvic recurrence. All patients had a digital rectal examination and a contrast enema to provide information about rectal stump length and distensibility, and to demonstrate the presence of a stricture or fistula.

Operative technique

Surgery was performed in the Lloyd-Davies position. The left colon was completely mobilized after division of the inferior mesenteric artery at its origin and division of the inferior mesenteric vein at the inferior border of the pancreas. This latter manoeuvre is important to allow complete mobilization of the left colon into the pelvis. The left colon was then transected using a stapler at a suitable healthy and well vascularized site. To ensure that there was sufficient colon to reach the anal verge, the length of the remaining colon was shown to extend at least 3 cm below the pubic symphysis. In five patients the left colon was absent, too short or devascularized due to insufficiency of Riolan's arcade. In these patients the transverse colon was brought down transmesenterically (two cases) or the inverted right colon was used (three). Suprarectal dissection was necessary to clear adherent small bowel or omentum.

The rectal stump was identified either by following the colon down to the complicated colorectal anastomosis or by using Hegar bougies passed transanally in the patients with a short Hartmann's stump. At that level, the rectal stump was often fibrotic and stuck to the sacrum or vagina. Rectovaginal fistulas were ignored and left *in situ*. In the presence of a rectovesical fistula, the bladder was either sutured externally or repaired from within the lumen. To preserve neighbouring pelvic structures, perirectal dissection was not attempted. The rectal stump was incised transversely over a bougie and rectal mucosectomy was started and conducted downwards as low as possible after submucosal infiltration with 1:50 000 saline–adrenaline solution.

Paper accepted 18 November 1997

The mucosectomy was then completed via a perineal approach from the dentate line upwards. The mucosal sleeve length was recorded in 24 operation notes, the mean length being 6·2 (range 3–12) cm. The rectal muscular sleeve left in place had to allow the passage of three fingers. If this was not possible, a vertical incision was made through the posterior rectal wall and long scissors were forced open in the upper rectum to stretch the pelvic fibrosis. Once the space within the rectal muscular sleeve was considered large enough, the stapled colon was delivered through this sleeve to the anus using triangular forceps. The opening of any previously ignored rectovaginal fistula was thereby obliterated by the new colon and allowed to heal spontaneously.

Four 4–0 reabsorbable sutures were placed at 12, 3, 6 and 9 o'clock to fix the colon in place and to avoid any tension on the anastomosis. The colon was transected at the level of the dentate line and a handsewn straight coloanal anastomosis was performed using 4–0 reabsorbable sutures and protected by a temporary loop ileostomy. The anastomosis was drained transanally for 48 h and two pelvic suction drains left in place for 3–6 days after surgery. The ileostomy was closed 6–8 weeks later, once clinical and radiological assessment of the anastomosis had been made. Patients were reviewed systematically at 1, 3, 6 and 12 months and then annually.

Results

Mortality and early morbidity

There was no perioperative mortality. Early surgical complications occurred in eight patients. One patient had postoperative pelvic bleeding requiring relaparotomy for haemostasis. One patient had a small bowel volvulus also requiring relaparotomy. Another developed a pelvic abscess which was drained transanastomotically under general anaesthesia.

Of the 18 patients who presented with fistulas, two developed recurrent rectovesical fistulas; one was successfully managed conservatively by transanal irrigation and a strict low-residue diet and the other required colectomy and repeat anastomosis. A third patient developed a recurrent rectovaginal fistula, which healed after reconstruction of a defunctioning colostomy.

One patient had a wound abscess after ileostomy closure. No patient complained of urinary retention or sexual difficulties. Medical complications included pulmonary embolism in one patient and urinary tract infection in three.

Long-term outcome

Two patients were lost to follow-up, at 2 months and 3 years. Three patients died from intercurrent disease at 3, 4 and 5 years, and one patient died from local recurrence and liver metastases at 3 years. Seven of the 28 patients who were followed developed eight late complications. Four patients developed incisional hernias, three at the ileostomy site and one along the laparotomy wound. Anastomotic strictures occurred in three patients who were all successfully treated by dilatation. One patient, who had had a Hartmann procedure for acute ischaemic colitis, developed ischaemic lesions within the transplanted colon 3 years after the Soave operation. This was treated conservatively and the patient did not require further surgery. Two patients who initially had cancer developed a second adenocarcinoma within the remaining colon, at 7 and 8 years.

Table 1 Symptoms at the end of follow-up in 23 patients

Symptom	No. of patients

Functional clinical results

Mean follow-up was 4·2 (range 1–16) years. Two patients of the 25 interviewed were still waiting for ileostomy closure; therefore function results were available for 23 patients (*Table 1*). In all but three patients, a clear improvement was demonstrable during the first postoperative year. At the end of follow-up, continence was abnormal in four patients. Poor results for continence did not appear to be related to age or pathology: the mean age of the four incontinent patients was 44 (range 37–59) years and initial pathology was a radiation-induced lesion in two, a colorectal complication in one and Hartmann's reconstruction in one.

Discussion

Rectal conditions such as severe irradiation injury to the rectum and pelvis[8–14], low colorectal anastomotic fistula or stenosis[15–17] and low Hartmann procedures[16] share the same features of the presence of an inflamed and fibrosed pelvis that renders perirectal dissection difficult and hazardous. Frequently, permanent colostomy is thought to be the only alternative in such conditions, as it was in the first 24 of the 30 patients in this series. Coloanal sleeve anastomosis has been advocated to manage these difficult conditions and preserve sphincter function.

Other conditions that render complete rectal wall excision hazardous because of the risk of haemorrhage include diffuse cavernous haemangioma of the rectum[18–20] and colitis cystica profunda[21]. In these cases Soave's procedure is a safe alternative to abdominoperineal excision of the rectum.

Mortality and morbidity in this series compare favourably with that in other series (*Table 2*). Fistulas recurred in three of 18 patients who had this complication at the time of Soave's procedure. Conservative treatment in one of these patients and reoperation in the other two led to complete healing in all cases. No patient complained of sexual urinary dysfunction, and this relatively low complication rate may be attributed to the operative technique itself, which avoids all deep pelvic dissection.

Long-term functional results in this series appear to be satisfactory, with 19 of 23 patients achieving normal conti-

nence. However, there remain a few patients who have continuing urgency, fragmentation of stools and a high frequency of defaecation. One explanation for this could be the decreased colonic distensibility in the fibrosed pelvis[22] due to irradiation, colorectal anastomotic complications or multiple previous operations. Cooke and Wellsted[10] reported the results of coloanal sleeve anastomosis in 59 patients operated on for radiation-induced rectal damage. The perioperative morbidity rate in this series was 24 per cent and there were four technical failures resulting in permanent colostomy. Of the 46 patients who had been followed for more than 1 year after closure of the colostomy, 35 were continent, seven had control of solid faeces but not of flatus or liquid stools, and four were completely incontinent. In contrast, only one patient in the present series was incontinent to stools. Similar results have been reported by other groups with satisfactory continence rates of 76 and 87 per cent following coloanal sleeve anastomosis performed for a variety of rectal conditions[2-9].

In conclusion, benign rectal conditions such as radiation-induced damage to the rectum, low colorectal anastomotic fistulas or stenosis, and reconstruction after low Hartmann procedures, may all be associated with difficult and potentially dangerous pelvic dissection. Soave's procedure obviates the need for extensive dissection of the lower rectum and offers good technical and functional success in both the short and long term.

Lack of telomerase in desmoids occurring sporadically and in association with familial adenomatous polyposis

D. K. SCATES, S. K. CLARK*, R. K. S. PHILLIPS* and S. VENITT

Background Telomerase activity may be required for unlimited growth of cells and is repressed in most somatic tissues, but is detectable in immortal cell lines, germ cells, many malignancies and some benign lesions. Desmoids are proliferative, locally invasive, non-metastasizing fibromatous tumours which rarely regress. They occur frequently in familial adenomatous polyposis (FAP), causing significant morbidity and death. Telomerase activity was assayed in desmoids from patients with and without FAP to assess the role of telomerase in the development of these lesions, and its potential as a prognostic marker and possible target for treatment.

Methods Protein extracts from 11 desmoids from nine patients with FAP, and ten desmoids from ten patients without FAP, were analysed for telomerase activity by the telomeric repeat amplification protocol, a sensitive polymerase chain reaction-based assay. Six fibrosarcomas and a fibrosarcoma cell line were used as positive controls; all displayed telomerase activity.

Results No telomerase activity was detected in any of the 21 desmoids studied.

Conclusion These results indicate that desmoid tumours are one of the intriguing exceptions to the emerging view that re-expression of telomerase activity accompanies the development of preneoplastic and neoplastic tissues, and suggest that alternative mechanisms may operate in these proliferative neoplasms.

Human telomeres are regions found at the ends of each chromosome which consist of the nucleotide sequence TTAGGG repeated up to 1000-fold. They appear to have two functions: the first is to protect chromosomes from recombination and loss; the second is to resolve the 'end-replication problem' which predicts the progressive and potentially catastrophic shortening of the 3′ end of DNA molecules over many cycles of replication, a problem imposed by the fact that DNA polymerization is initiated from the site of a bound RNA primer and can proceed only in the 5′ to 3′ direction. This problem is overcome by telomerase, a ribonucleoprotein that synthesizes TTAGGG telomeric repeat sequences and fuses them to the 3′ terminus of the chromosome[1–3].

It has been suggested that shortening of telomeres with cell division in the absence of telomerase activity may provide a mechanism to limit the proliferative capacity of normal cells, which senesce and stop dividing after undergoing a given number of cell divisions[3–5]; conversely, activation of telomerase may be required to allow cells to escape from senescence and to proliferate indefinitely. This is supported by the finding that there is no telomerase activity in most human somatic cells, whose telomeres shorten with replicative age[6], and that telomerase activity is present in germ cells and many malignant tumours and immortal cell lines[3,7–12].

Desmoid tumours are rare, but are an important extracolonic manifestation of familial adenomatous polyposis (FAP). They have been reported to occur in about 10 per cent of patients with FAP[13–15] and are one of the two commonest causes of death in patients who have had prophylactic colectomy for this condition[16,17]. They may occur at any site, but show a propensity for the small bowel mesentery, retroperitoneum and abdominal wall in FAP[18].

The pathogenesis of desmoid tumours is not clearly understood. They are classified as fibromatoses[19], which result from infiltrative proliferation of well differentiated fibroblasts, and show repeated local recurrence but no features of unequivocal malignancy or inflammation. Desmoid tumours are locally invasive, but do not metastasize. The only convincing report of malignant transformation (to fibrosarcoma) occurred in a desmoid treated with radiotherapy[20]. There is evidence that desmoids are clonal in composition[21] and carry a 'second hit' mutation in the *APC* gene, and therefore are true neoplasms[22–25].

The levels of telomerase activity have been assayed in specimens of desmoid tumours from patients with and without FAP to assess the role of telomerase in the development of these lesions, and its potential as a prognostic marker and possible target for treatment.

Patients and methods

Patients

A total of 11 desmoid tumours from nine patients with FAP, ten desmoid tumours from ten patients without FAP and six fibrosarcomas were analysed for telomerase activity. Details of the patients from whom specimens were taken are given in *Table 1*. All of these tumours were sufficiently large and symptomatic to require surgical treatment.

Presented to the Surgical Research Society meeting, London, UK, January 1997, the European Council of Coloproctology meeting, Edinburgh, UK, June 1997 and to the Association of Surgeons of Great Britain and Ireland meeting, Bournemouth, UK, April 1997, and published in abstract form as *Br J Surg* 1997; **84**(Suppl 1): 58–9; *Int J Colorectal Dis* 1997; **12**: 117; and *Br J Surg* 1997; **84**: 725.

FAP, familial adenomatous polyposis; n.a., Data not available

Preparation of lysates

After excision the samples were snap frozen in liquid nitrogen and stored at −80°C. Each specimen (50–100 mg) was homogenized in 200 µl 3-[(3-chloramidopropyl)dimethylamino]-1-propanesulphonate lysis buffer (Sigma, Poole, UK). After 25 min on ice the lysate was centrifuged at 16 000 *g* for 20 min at 4°C. The supernatant was quickly frozen on dry ice and stored at −70°C. The protein concentration of the extract was measured using a micro protein determination kit 610-A (Sigma). Extracts of the fibrosarcoma cell line HT1080 were prepared by washing cells in phosphate buffered saline, collecting by centrifugation, resuspending in ice cold wash buffer (HEPES–potassium hydroxide (pH 7·5) 10 mmol/l, magnesium chloride 1·5 mmol/l, potassium chloride 10 mmol/l, dithiothreitol 1 mmol/l), collecting again by centrifugation and then resuspending in 20 µl ice cold lysis buffer per 10^6 cells. After 30 min on ice the lysate was centrifuged at 100 000 *g* at 4°C. The supernatant was processed in the same way as the tissue extracts.

Assay for telomerase activity

Telomerase activity was assayed by the telomeric repeat amplification protocol (TRAP)[8]. Positive controls for the TRAP assay consisted of the six fibrosarcomas and a fibrosarcoma cell line (HT1080) known to contain active telomerase. Aliquots of extracts containing 6 µg protein were incubated for 10 min at room temperature in Tris–hydrochloride (pH 8) 20 mmol/l, magnesium chloride 1·5 mmol/l, potassium chloride 63 mmol/l, 0·005 per cent Tween, ethylene glycol-bis(b-aminoethyl ether)-N,N,N′,N′-tetra-acetic acid 1 mmol/l, 1 µg T4g32 protein (Pharmacia, St Albans, UK), 2′-deoxyribonucleoside 5′-triphosphates 50 mmol/l, 4 µg bovine serum albumin, 0·1 µg TS oligonucleotide (5′AATCCGTCGAGCAGAGTT-3′) and 3 µCi [^{32}P]2′-deoxycytidine 5′-triphosphate (3000 Ci/mmol) to allow for extension of oligonucleotide TS by telomerase. Some 0·1 µg CX primer (5′-CCCTTACCCTTACCCTTACCCTAA-3′) and 2 units Taq polymerase were then added and the reaction mixture was subjected to 27 polymerase chain reaction cycles at 94°C for 30 s, 50°C for 30 s and 72°C for 90 s. Half of the product (25 µl) of each reaction was analysed by electrophoresis in 0·5 × Tris-borate ethylenediamine tetra-acetic acid on 10 per cent polyacrylamide non-denaturing gel. Gels were dried and autoradiographed at −70°C with intensifying screens for up to 40 h. Telomerase activity was detected as a six-nucleotide repeat ladder. Extracts were considered negative if no telomerase products were detected after a 40-h exposure.

The experiments were repeated, incubating 5 µl of all cell extracts with 1 µg RNase A (Sigma) for 15 min at 37°C, before subjecting them to the TRAP assay. Desmoid samples were re-assayed using a volume of cell extract equivalent to 60 µg and 0·6 µg protein, and extracts from the positive control cell line HT1080 were subjected to the TRAP assay after the addition of desmoid cell extract equivalent to 6 µg protein.

Results

Telomerase activity was not detected in any of the desmoid samples under standard TRAP assay conditions using a volume of cell extract containing 6 µg protein (*Fig. 1*). However, all six of the fibrosarcoma samples were found to express telomerase activity. This was shown to be sensitive to ribonuclease (RNase) since incubation of cell extract with RNase A resulted in elimination of this activity, as it did in the fibrosarcoma cell line HT1080 extract (*Fig. 2*).

The inability to detect telomerase activity in desmoid extracts may be a true indicator of the absence of telomerase activity or could result from the presence of inhibitory factors, as reported by others[7,10]. When desmoid samples were re-assayed using a tenfold increase in concentration of extract in order to allow detection of weak telomerase activity, or ten-fold dilutions, on the assumption that putative inhibitors would be diluted away, telomerase activity was not detected (data not shown). Addition of desmoid extracts to extracts from the positive control cell line, to determine whether the desmoid

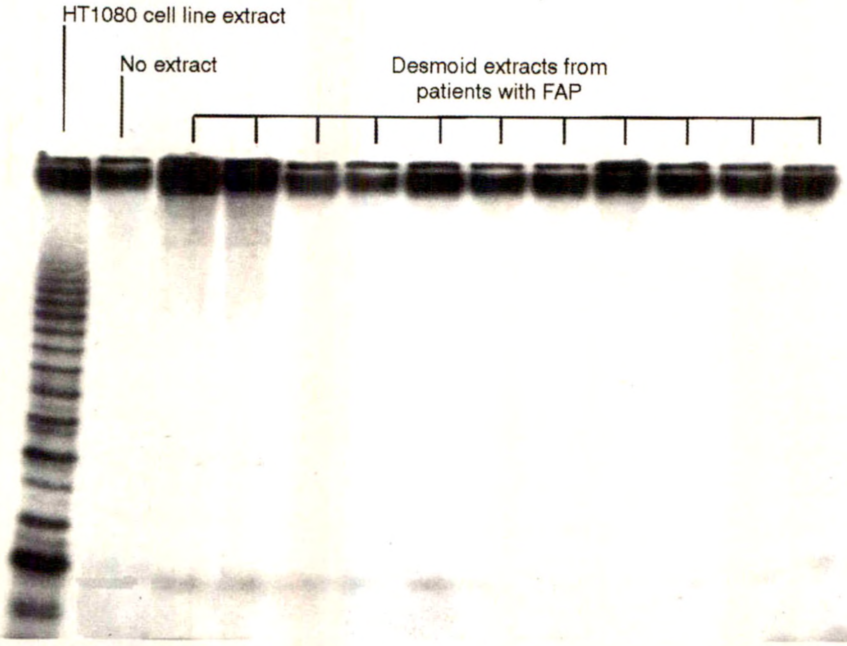

Fig. 1 Lack of telomerase activity in cell extracts from desmoid samples from patients with familial adenomatous polyposis (FAP). An extract from the fibrosarcoma cell line HT1080 served as a positive control, producing the characteristic six-basepair ladder. The negative control contained no extract

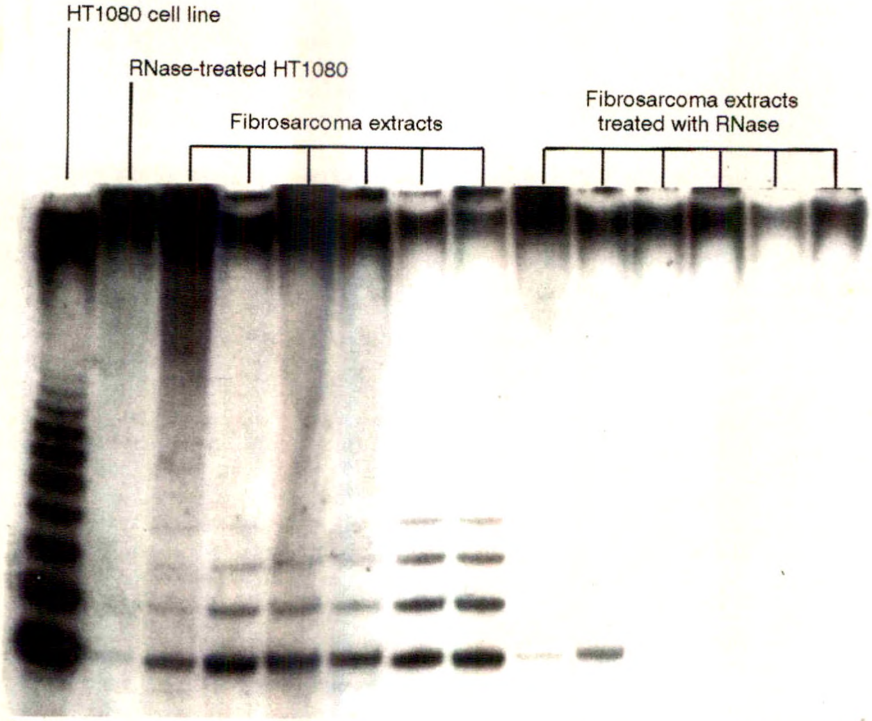

Fig. 2 Telomerase activity in extracts from fibrosarcoma samples. Treatment with RNase before analysis in the telomeric repeat amplification protocol resulted in elimination of the six-basepair ladder in all of the fibrosarcoma extracts and in the HT1080 extract

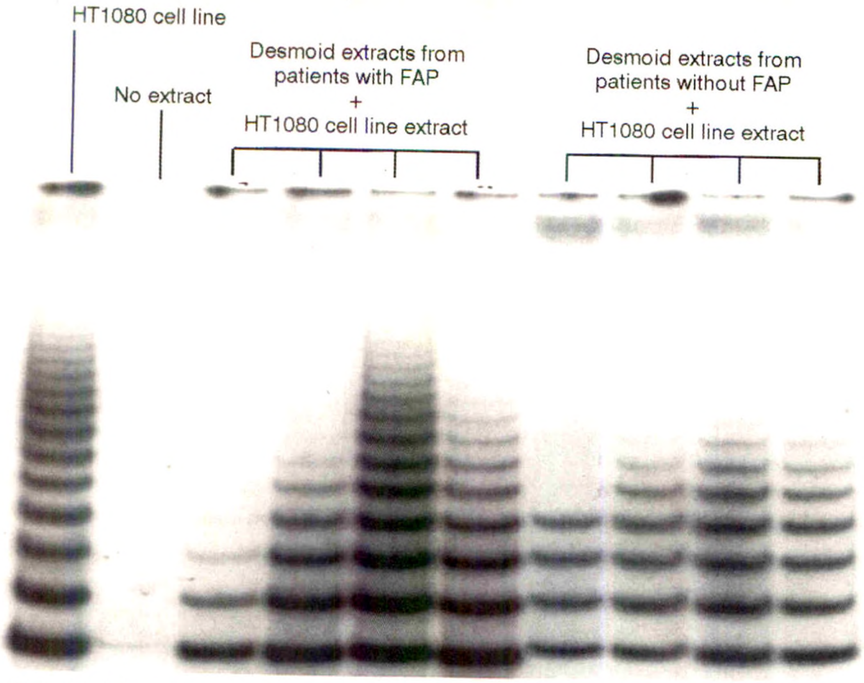
extracts could inhibit telomerase activity of the positive control, did result in a reduction of the telomerase signal in four of the 11 desmoid samples from patients with FAP and two of the ten desmoid samples from those without FAP (*Fig. 3*). This suggests that some of the desmoid extracts did indeed contain inhibitory factors, either to telomerase activity or to the TRAP assay. However, these inhibitory factors were not strong enough completely to



HT1080 cell line

Desmoid extracts from patients without FAP + HT1080 cell line extract

Fig. 3 Examples of the effect of adding cell extracts from desmoid samples to extracts of the positive control. FAP, familial adenomatous polyposis

inhibit the telomerase signal. It is unlikely, therefore, that any of the desmoid extracts gave false-negative results for telomerase activity.

Discussion

These results demonstrate that telomerase activity was not present in the desmoids investigated, whether they originated in patients with or without FAP, and that the inability to detect telomerase activity could not be accounted for by inhibition of the assay by cell extracts. Moreover, although desmoids show varied cellularity, it is unlikely that this result could have been caused by a lack of cells in the tissues studied as the TRAP assay is highly sensitive, detecting telomerase activity in as few as 100 positive cells or as few as 0·001 per cent positive cells in a mixed population[8]. That telomerase activity can be re-expressed in malignant tissue of fibroblastic origin was demonstrated by the fact that all of the six fibrosarcomas gave strongly positive results in the TRAP assay.

Although desmoids do not display unequivocal features of malignancy and do not metastasize, they can exhibit aggressive local invasion and recurrence and can grow to a very large size. Desmoids from patients with FAP display certain features of neoplasia, the most notable being the loss of both normal alleles of the *APC* gene, one copy being lost by germline mutation and the second by somatic mutation or by microdeletion[25,26], in common with colorectal adenomas and cancers in FAP. It appears, therefore, that somatic mutation of the *APC* gene is an early and crucial event in the formation both of adenomas and desmoids, since mutations in other genes known to be involved in the development of colorectal cancer, such as K-*ras* and *TP53*[27], are very rare or absent in adenomas and desmoids[25,28].

Studies of other neoplastic but non-malignant tissues indicate that re-expression of telomerase activity is by no means unknown. For example, Tahara *et al.*[7], using specimens from patients without FAP, detected telomerase activity in colorectal and gastric adenomas and gastric intestinal metaplasia, and concluded that reactivation of telomerase may occur at an early stage of carcinogenesis. However, in another study[29] there was no detectable telomerase activity in colorectal or duodenal polyps from patients with FAP or in colonic polyps from patients with colon cancer but not FAP. These authors concluded that detectable telomerase activity correlates with acquisition of malignancy from benign adenomatous polyps to invasive colorectal cancer. Hepatitic and cirrhotic liver[30], skin papillomas[31], and dysplastic and hyperplastic head and neck lesions[32] are other potentially premalignant tissues found to express some telomerase activity. Low levels of activity have also been reported in breast fibroadenomas[9]. Sun-damaged skin expresses higher telomerase activity than does normal skin, but lower activity than is found in basal cell carcinomas, squamous cell carcinomas and melanomas[33]; in neuroblastomas, telomerase is generally expressed at low levels in tumours with a favourable prognosis and at very high levels in tumours with an unfavourable prognosis[11]. Thus there is evidence for the lifting of telomerase repression in some regenerative lesions and benign tumours as well as frank malignancy. Conversely, a significant proportion of retinoblastomas (50 per cent)[34] and glioblastomas (25 per cent)[35] have been shown to develop in the absence of telomerase activity. This may be possible because they arise at a young age when telomeres are still relatively long, or they may follow an alternative pathway of telomere maintenance.

The extent to which the 21 desmoids examined in this study are typical of desmoids in general, in that they do not express telomerase activity, requires further study. However, the present results suggest that desmoid tumours are one of the intriguing exceptions to the emerging pattern that re-expression of telomerase activity accompanies the formation of regenerative, preneoplastic and neoplastic tissues. The lack of telomerase activity in desmoids suggests that mechanisms, currently unknown, other than reactivation of telomerase activity may operate in these proliferative neoplasms.

Acknowledgements

The authors thank Mr R. Grimer (Consultant Surgeon, Royal Orthopaedic Hospital, Birmingham) and Professor C.S. Cooper (Section of Molecular Carcinogenesis, Institute of Cancer Research) for supplying some of the specimens for this study, and Professor A.D. Spigelman for valuable discussions and advice. Background Desmoid tumours occur in about 10 per cent of patients with familial adenomatous polyposis (FAP), and are an important cause of morbidity and death. The natural history of desmoids was investigated by documenting prospectively the prevalence and progression of possible precursor lesions.

Methods A group of patients with FAP and controls were examined at laparotomy. Another group, with FAP and no clinical evidence of desmoid, and a group of controls, underwent abdominopelvic computed tomography.

Results At laparotomy 13 of 42 patients with FAP had fibromatous mesenteric plaques; seven of these had not had surgery. Seven had more extensive mesenteric fibromatosis and had undergone significantly more laparotomies than the rest. Of 103 patients scanned, two had desmoid tumours and 22 (21 per cent) had mesenteric fibromatosis. On follow-up both desmoid tumours grew rapidly; mesenteric fibromatosis was unchanged in eight and resolved in four of the 12 patients rescanned.

Conclusion A model of desmoid tumour development is suggested, analogous to the adenoma–carcinoma sequence, in which a less benign phenotype emerges as molecular genetic abnormalities accumulate: mesenteric plaque-like desmoid precursor lesions arise in many patients with FAP before surgery as a result of abnormal fibroblast function; some, perhaps stimulated by surgery, progress to mesenteric fibromatosis; these in turn can give rise to desmoid tumours.

Familial adenomatous polyposis (FAP) is an autosomal dominantly inherited disorder due to germline mutation of the tumour suppressor gene *APC*, which occurs with a frequency of one in 7500[1]. Multiple large bowel polyps usually develop in adolescence or early adulthood, with inevitable progression to colorectal carcinoma if not treated; affected individuals are managed either by prophylactic restorative protocolectomy (RPC) or colectomy and ileorectal anastomosis (IRA) with surveillance of the rectal remnant.

Desmoid tumours are one of a range of extracolonic manifestations of FAP, and have been reported to occur in about 10 per cent of these patients[2]. They are poorly understood, locally invasive, non-metastasizing neoplasms[3] which occur particularly in the small bowel mesentery. Intra-abdominal desmoid tumours are an important source of morbidity in FAP, and are one of the commonest causes of death in these patients[4,5]. Treatment is difficult and based largely on anecdote; it has been suggested that medical treatment of very early desmoids might be more effective[6].

There is evidence that trauma (particularly surgical), oestrogens and genetic factors all have a role in desmoid formation[2], and somatic mutation of the *APC* gene has been documented in these tumours[7–11]. However, their precise aetiology and natural history remain obscure. Areas of diffuse mesenteric fibromatosis have been observed in patients with FAP, and it has been suggested that these might enlarge to form a desmoid tumour[12]. Such progression has been observed in a retrospective study in which computed tomography (CT) scans of patients subsequently diagnosed with desmoid tumour were reviewed[13]; mesenteric stranding or whorled mesenteric thickening (*Fig. 1*), sometimes associated with bowel tethering, was seen to progress to form a desmoid

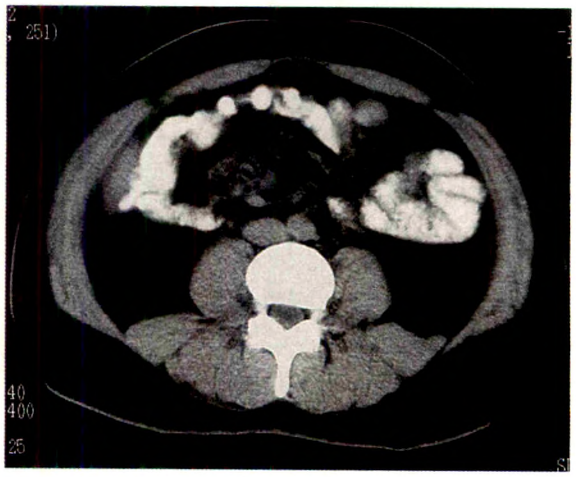

Fig. 1 Computed tomography scan showing whorled mesenteric thickening, compatible with mesenteric fibromatosis

tumour. However, the origin of these abnormalities and the frequency with which they occur or give rise to desmoid tumours in patients with FAP is not known. This prospective study was undertaken to identify early abnormalities in the small bowel mesentery of patients with FAP and to document their subsequent progression.

Patients and methods

Intraoperative examination

A detailed examination was made of the small bowel mesentery of all patients with FAP undergoing laparotomy over a period of 18 months. In addition, a group of control patients, without FAP, undergoing laparotomy was examined in the same way. Biopsies of abnormal areas were taken for histological examination

Computed tomography screening

Patients with FAP were recruited at outpatient visits; those who were under 16 years old, pregnant, had symptoms suggestive of desmoid (abdominal pain or awareness of an abdominal mass), with an abdominal mass on clinical examination or with a diagnosis of desmoid in the past were excluded. The patients underwent helical abdominopelvic CT with oral contrast. A control group of eight volunteers underwent a limited CT examination of the abdomen, specifically to image the small bowel mesentery. These patients had been treated for chronic constipation by total colectomy and did not have FAP. All the scans were reported by two consultant radiologists specialized in cross-sectional imaging; the results were reached by consensus. Patients with evidence of desmoid tumour or mesenteric fibromatosis were invited for a single repeat CT scan after approximately 6 months. Approval for this study was obtained from the Harrow Research Ethics Committee and the East London and City Health Authority Research Ethics Committee, and written informed consent was obtained from all subjects.

Results

Intraoperative examination

Forty-two patients with FAP (median age 28 (range 13–53) years; 23 male) and 13 controls were examined at laparotomy. There was no significant difference between these groups in terms of age, sex or number of previous laparotomies. Seventeen patients with FAP had mesenteric abnormalities, consisting of plaque-like areas of peritoneal thickening (*Fig. 2*) in ten and of mesenteric fibromatosis in four; a further three patients had both types of abnormality. All but two of these lesions were biopsied and were found to be histologically compatible with desmoid. The only abnormality in the control group was a small peritoneal streak seen in one patient ($P < 0{\cdot}05$, two-tailed Fisher's exact test).

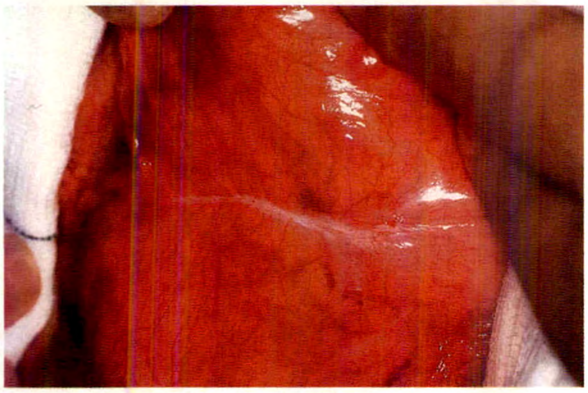

Fig. 2 Fibromatous plaque on small bowel mesentery

Seven of the ten patients with FAP with a plaque only had not had abdominal surgery, whereas all of those with mesenteric fibromatosis had a history of at least one laparotomy. Those with mesenteric fibromatosis had undergone more laparotomies (mean(s.d.) 2·0(1·0)) than those without (0·4(0·7)) ($P = 0{\cdot}001$, Mann–Whitney *U* test). There was no relationship between patients' age, sex, parity or oral contraceptive use and the findings at laparotomy; none of these patients had a family history of desmoid.

Computed tomography screening. One hundred and three patients with FAP (median age 36 (interquartile range 30–48) years; 54 (52 per cent) men) were investigated. Two were found to have a clinically unrecognized desmoid tumour and a further 22 (21 per cent) had mesenteric abnormalities consisting of stranding or whorled thickening, similar to those described by others[13], and compatible with mesenteric fibromatosis. None of the control group had any abnormality.

Both patients with a desmoid tumour were within 3 years of surgery and become symptomatic within 8 weeks of CT, before being informed of the findings. Patients with abnormalities consistent with mesenteric fibromatosis had laparotomy a median of 6 (range 1–19) years previously, significantly more recently than those with a normal CT scan (median 10 (range 1–42) years) ($P = 0{\cdot}03$, Mann–Whitney *U* test). Mesenteric abnormalities were found on CT in 27 per cent of female compared with 20 per cent of male patients, in 32 per cent of women with a history of combined oral contraceptive use compared with 13 per cent of those without, and in 33 per cent of parous women compared with 16 per cent of nullipara, although none of these differences reached statistical significance. Both the patients found to have a desmoid tumour were women, and both had children. Only four patients had a first-degree relative with desmoid; two of these were found to have mesenteric fibromatosis compared with 20 of the 99 patients with no such family history.

One hundred patients (97 per cent) had already undergone prophylactic colectomy. The three patients who had never had a laparotomy had normal CT scans. Sixteen (21 per cent) of the 75 patients who had only undergone IRA had diffuse mesenteric change, compared with three of the eight who had had RPC, and two of the six who initially had IRA and later had restorative proctectomy. Both patients with desmoid tumour had undergone IRA, one laparoscopically assisted. Patients with mesenteric fibromatosis had their first laparotomy at a slightly younger age (mean(s.d.) 21(10) years) than those without (25(11) years), and had had on average more laparotomies. None of these differences was significant.

Both of the patients with desmoid tumour and 12 of those with diffuse mesenteric change have been followed up by repeat CT scanning after a mean of 10 (range 3–20) months. Both the desmoids grew rapidly. The mesenteric fibromatosis was unchanged on follow-up in eight patients and had resolved in four.

Four patients took part in both studies. Both of the patients scanned before operation had normal findings at subsequent laparotomy. One patient who had normal findings at laparotomy had a normal CT scan 8 months later, and another patient, found to have a peritoneal plaque at laparotomy, had mesenteric fibromatosis when scanned 7 months later.

Discussion

Desmoid tumours follow a variable and unpredictable course, and can resolve spontaneously[14]. Lesions of mesenteric fibromatosis, consisting of mesenteric thickening and puckering but not amounting to a mass, have been seen at laparotomy in patients with FAP[12] and their CT appearances and progression to intra-abdominal desmoid tumours have been documented[13]. That CT changes such as these were found in none of the eight patients without FAP who had undergone IRA confirms that they are unlikely to be simply a consequence of this extensive surgery.

Fibroblasts cultured from skin biopsies of patients with FAP have been shown to exhibit reduced growth inhibition[15–17], and these patients develop uglier scars and more adhesions after laparotomy than the normal population[18]. The authors suggest that the mesenteric plaques observed are desmoid precursor lesions (DPLs), and that they form as a result of this abnormality of fibroblast function. These lesions are too small to be visualized by CT. That DPLs were found at laparotomy in 13 of 42 patients, half of whom had not had previous abdominal surgery, shows that they can arise in the absence of surgical trauma.

More extensive mesenteric fibromatosis was found in seven of 42 patients at laparotomy and in 21 per cent on CT, all in patients who had undergone abdominal surgery in the past. This, and the finding that patients with mesenteric fibromatosis at laparotomy had a significantly greater number of previous abdominal operations, suggests that surgery may promote the development of DPLs to the next stage of more extensive mesenteric fibromatosis. Of note in this context was the finding that the only patient with mesenteric plaques at laparotomy to have undergone CT subsequently was found to have developed mesenteric fibromatosis. It must not be forgotten, however, that both mesenteric fibromatosis and desmoid tumour can occur in patients who have never had abdominal surgery[19,20]. The reported lifetime incidence of desmoid tumour in patients with FAP is about 10 per cent in most series[2], implying that only some cases of mesenteric fibromatosis will go on to form a desmoid tumour. Moreover, the follow-up data suggest that some of these abnormalities have actually regressed over the course of this study.

Possible trends towards increased mesenteric fibromatosis formation in those with a strong family history, in women compared with men, and in parous women and oestrogen-containing contraceptive users, observed in these data are compatible with the same aetiological factors being at work in the formation of these lesions as have been described in desmoid tumours presenting clinically.

It has been suggested that RPC is associated with a higher rate of subsequent desmoid formation than IRA because of the greater surgical trauma, and that surgery at a younger age also carries an increased risk; as a result there is considerable controversy over the optimal surgery and its timing in these patients. Again the present data are compatible with this hypothesis but the sample size of this study was not sufficient to show any significant difference in the rate of desmoid formation between patients having IRA and RPC; in particular there appeared to be no difference in desmoid formation between those having RPC as their primary procedure and those having conversion to restorative proctectomy following an initial IRA.

The findings that patients with mesenteric fibromatosis on CT had abdominal surgery significantly more recently than those with a normal scan, and that the only two patients found to have a frank desmoid tumour at screening both developed clinically apparent desmoid within 2 months, are consistent with the observation that most desmoid tumours develop in the first 5 years after laparotomy. In patients who had prophylactic surgery several years before, mesenteric fibromatosis will have either progressed to clinically apparent desmoid, resulting in exclusion from this study, or will be stable or regressing. That mesenteric thickening was seen up to 19 years after laparotomy shows that these changes can persist long after other postoperative reaction in the abdomen has resolved.

In the light of the findings of this study, a model of desmoid tumour development is proposed in which DPLs form in a substantial proportion of patients with FAP before surgery, as a consequence of abnormal fibroblast function due to germline *APC* mutation; some of these progress to mesenteric fibromatosis, a change which may be promoted by surgical trauma. In some, but not all, cases this in turn can progress to form a desmoid tumour. Once a mass had formed, growth appears to be rapid, at least initially. Whether oestrogens and genetic factors influence the development of mesenteric fibromatosis from DPLs, or of desmoid tumour from mesenteric fibromatosis, or both, is not clear. This model is in many ways analogous to the adenoma–carcinoma sequence seen in the large bowel[21]; there is evidence of somatic mutation and allele loss at *APC* accompanying phenotypic change, but the stage at which this occurs and what other changes are involved remain to be elucidated.

Many of the cases of mesenteric fibromatosis detected will never develop into a desmoid tumour, and may never cause symptoms, although their presence may prevent restorative surgery. CT screening of asymptomatic patients with FAP to allow early treatment of desmoids has been suggested, but the variable progression of mesenteric fibromatosis to desmoid tumour and the rapid growth of established desmoid tumours suggests that CT appearances may give rise to unnecessary concern and add little to clinical follow-up. However, these patients need to be monitored for research purposes to document what progression does take place, and perhaps to study the effects of early treatment.

Acknowledgements

The authors thank Nicky Fry and Andrew Martin for performing the CT scans, and Kay Neale and Judith Landgrebe of the St Mark's Polyposis Registry for help and advice. S.K.C. is supported by the Imperial Cancer Research Fund.

Malone antegrade continence enema for faecal incontinence and constipation in adults

K. KROGH and S. LAURBERG

Surgical Research Unit, Department of Surgery L, Section AAS, University Hospital of Aarhus, Tage Hansensgade 2, 8000 Aarhus C, Denmark
Correspondence to: Dr K. Krogh

Background In the Malone antegrade continence enema (ACE) technique the appendix or a 'neoappendix' created from the caecum is brought to the abdominal wall creating a small stoma. Thereby, antegrade enemas can be administered to empty the colorectum and prevent faecal incontinence or constipation in children with congenital malformations. The aim of this study was to describe the results of the ACE in adults suffering from faecal incontinence or constipation.

Methods In 16 adult patients (ten women and six men) suffering from severe faecal incontinence (ten patients) or constipation (six patients) the ACE procedure was performed; the appendix was used in 12 and a 'neoappendix' was created in four. Patient records were used for the description of surgical procedures and complications. Results were evaluated by a structured telephone interview.

Results After a follow-up of 1–39 (mean 17) months, four patients had stopped using the stoma because of abdominal pain or lack of effect. Among the other 12 patients overall satisfaction with the stoma was high or very high. In constipated patients mean time for defaecation was reduced from 170 to 45 min. Faecal incontinence was much reduced in eight patients; the impact on social activities and quality of life caused by bowel dysfunction was reduced in all 12 patients.

Conclusion The ACE technique can be used to treat selected adult patients suffering from faecal incontinence or constipation.

In 1990 Malone *et al.*[1] described the antegrade continence enema (ACE) technique, creating a continent stoma by implanting the tip of the appendix in a non-refluxing manner into the caecum and bringing the base out onto the abdominal wall. Through this small appendicostomy, antegrade enemas could be administered to empty the colorectum and prevent faecal incontinence or constipation. In several studies the ACE has been safe and effective among children suffering from faecal incontinence or chronic constipation due to spina bifida or anorectal malformation[2–5]. Later reports have indicated that reimplantation of the appendix to avoid faecal leakage is unnecessary and most authors simply bring out the tip of the appendix[2–4,6]. The operation can be performed synchronously with bladder reconstruction[2,7] and the technique has been modified by creating a 'neoappendix' from a tubularized caecal flap as an alternative in patients without an appendix[7,8].

Although many adult patients may benefit from the ACE, results of its use in adults have only been presented in a single study. Thus, Hill *et al.*[6] performed the operation in six adult women suffering from severe slow transit constipation. Results from the procedure in adult patients suffering from faecal incontinence have never been described. If useful, it may relieve symptoms in patients suffering from faecal incontinence or chronic constipation due to spinal cord lesions, spina bifida, cerebral palsy or thrombosis, lesions to the anal sphincters, slow transit constipation and systemic sclerosis. Therefore, more studies of the results of the ACE in adults are necessary.

Paper accepted 6 January 1998

Patients and methods

From January 1993 to June 1996, 16 patients underwent the ACE procedure. There were ten women and six men aged 20–68 (mean 41) years. The clinical problem was faecal incontinence in ten patients and chronic constipation in six (*Table 1*).

Faecal incontinence was caused by cerebral thrombosis or palsy (two patients), spinal cord lesions (two patients with lesions at T2 and L1), lumbar myelomeningocele (one patient), and systemic sclerosis (one patient). In four patients faecal incontinence was due to complicated anal sphincter lesions caused by fistulas (two patients), traumatic anal injury from a motorcycle accident (one) and haemorrhoidectomy (one). Anal sphincter damage was evaluated by anal manometry and anal ultrasonography. In three patients the damage was too severe to allow sphincter reconstruction and in one patient sphincter reconstruction had failed.

Chronic constipation was caused by spinal cord lesions (two patients; one with a lesion at C5 and one with a lumbar lesion following five operations for disc prolapse), slow transit constipation, systemic sclerosis and obstructed defaecation (one

patient each). One patient suffered from constipation and severe chronic abdominal pain after a radical hysterectomy and had attempted suicide 6 months previously because of these symptoms. The suicide attempt had resulted in a hemiparesis further worsening constipation and abdominal pain.

All patients had been treated with increased fibre intake and laxatives or suppositories for several years without effect.

Patients' records were used to ascertain the indications for the procedure, surgical procedure and postoperative complications. Thirteen patients available for follow-up underwent a structured telephone interview to describe symptoms before treatment and at follow-up, bowel emptying procedures and satisfaction with the result. The follow-up period was 1–39 (mean 17) months. Results for three patients, not available for follow-up and no longer using the procedure, were drawn from hospital records.

Interviews were taped and a questionnaire was filled out by the interviewer during the interview. To minimize observer bias the interviewer (K.K.) was not the one who had operated on the patients.

Surgical procedures

Standard bowel preparation and prophylactic antibiotics were given. A midline incision was used and, in 12 patients with an appendix, the tip of the appendix was delivered through a right iliac fossa incision. Then a small stoma was created from the appendix using a V-Y plasty in the skin[2] (*Fig. 1*), and the caecum was fixed to the abdominal wall. One patient had a bladder augmenting procedure during the same operation.

In four patients without an appendix a 'neoappendix' was created for the procedure from a tubularized caecal flap as described previously[6,8]. All procedures were performed by the same surgeon (S.L.).

Following both procedures a silicone catheter (6 or 8 Fr) was left *in situ* for 2 weeks. Colonic wash-outs were started after 10 days.

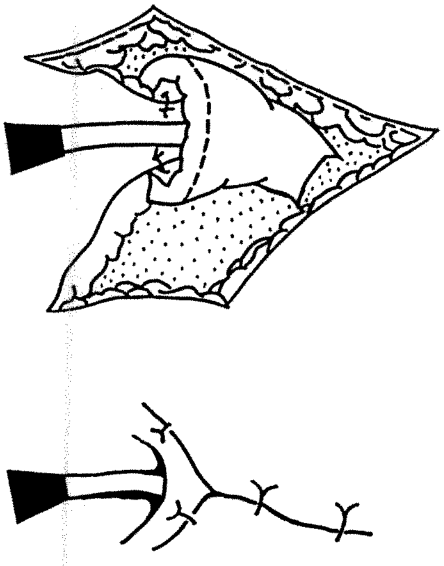

Fig. 1 Creation of a stoma from the appendix using a V-Y plasty in the skin. The V-Y plasty increases the diameter of the outer opening of the stoma and embeds it in a cutaneous fold. A silicone catheter is left in the lumen of the stoma for 2 weeks

Results

Complications

Superficial infection around the outer opening of the stoma occurred in four patients, but all were successfully treated with oral antibiotics for a few days.

Stenosis of the appendicostomy occurred in four patients. These were all treated using Hegars dilators up to three or four times. In one of these patients the stoma was revised. Stenosis of the stoma resulted in one patient discontinuing its use because of abdominal pain during wash-outs. During the operation it had been noted that the patient had a very narrow appendix possibly explaining the complication.

Faecal incontinence

Among ten patients having the ACE because of faecal incontinence six were still using the stoma at follow-up. One patient with sphincter lesions due to fistula surgery had stopped using the appendicostomy after 3 months because he was no longer incontinent even if he did not use it. One patient with disseminated mammary cancer had become too weak to perform the daily procedure. She was, however, very satisfied with the stoma because she had not suffered from faecal incontinence while using it.

Two patients had stopped using the stoma because of abdominal pain during wash-outs; in one of these this was caused by stenosis of the stoma

Among the six patients still using the stoma, five had suffered from faecal incontinence daily and one several times each week before the operation. At follow-up the frequency of incontinence episodes was much reduced in all six patients. Thus, two patients were never incontinent, three were incontinent less than once every month and one was incontinent once or more every week. Five patients used pads before the operation, but only one continued to do so at follow-up.

Constipation

Four of six patients operated on for constipation or obstructed defaecation still used the stoma at follow-up. One patient suffering from systemic sclerosis experienced no effect of the treatment. The patient who suffered from constipation and severe neurogenic abdominal pain due to a radical hysterectomy and hemiparesis had not yet tried using the stoma at follow-up because of pain around the site of incision.

Among the four patients still using the ACE, mean time for defaecation was reduced from 170 to 45 min. All felt that their problems from constipation were very much improved since the operation.

Use of the antegrade continence enema and patient satisfaction

Among the ten patients still using the stoma, four used it every day, five every second day and one every third day. Time taken to perform the enema was 15–60 (mean 30) min. All used tap water, two adding a phosphate enema to this. The volume of water used was 500–2000 (mean 967) ml. One patient with tetraplegia needed help for the procedure.

Abdominal discomfort during the enema was experienced by four patients. Five patients regularly had reflux of small amounts of water and faeces after wash-outs; however, in all five this could be controlled by an ordinary plaster. Four patients occasionally had reflux of small amounts of air from the appendicostomy. No patient felt that the appendicostomy was a major cosmetic or psychological problem.

Before the operation nine of these ten patients felt that colorectal dysfunction imposed a major restriction on their quality of life or social activities and one patient reported some restriction. At follow-up one reported that colorectal dysfunction caused some restriction while nine reported little or no restriction.

Overall satisfaction was very high in eight and high in two of the ten patients still using the procedure. Furthermore, two patients no longer using the stoma because the symptoms had disappeared or because of serious illness were very satisfied with the procedure. Thus, 12 of 16 patients operated were satisfied with the result.

Patients still using the ACE were asked to compare bowel function before the operation and at follow-up, using a scale in which 0 was the worst possible and 100 ideal. Before operation the mean score was 12 (range 0–30) while at follow-up it was 85 (range 70–100).

In the subgroup of patients with colorectal problems due to neurogenic lesions (seven patients) satisfaction with the ACE was high or very high in the six patients still using it. Among four patients with faecal incontinence due to complicated anal sphincter lesions patient satisfaction was high or very high in the three patients still using the stoma. In the mixed group of five patients with severe colorectal problems caused by systemic sclerosis, slow transit constipation, obstructed defaecation or hysterectomy the procedure was successful in three.

Discussion

This study shows that the Malone antegrade continence enema is a safe and effective treatment for selected adult patients suffering from severe faecal incontinence or constipation. Overall, the ACE was successful in 12 of 16 patients over a mean follow-up of 17 months. This is in accordance with some previous results from children suffering from faecal incontinence[2], while others have reported a higher success rate but after a shorter follow-up[3,6,7].

These preliminary results indicate that the ACE can relieve colorectal problems in patients with neurological lesions who often suffer from severe constipation or faecal incontinence[9,10]. Furthermore, the results in patients with incontinence due to severe anal sphincter lesions or neurological lesions are comparable to results from the creation of a neosphincter from the gracilis muscle[11,12] or the implantation of an artificial anal sphincter[13,14]. Therefore, the ACE technique, as a smaller operation, may be an alternative to these more extensive procedures. Furthermore, no major complications were observed and if patients find the side-effects unacceptable they can discontinue using the stoma. It will then obliterate, leaving the patient no worse than before the operation.

As in previous studies, the present results indicate that reimplanting the appendix is unnecessary. The tip of the appendix was simply brought out. The rate of success was higher among patients having an appendicostomy (ten of 12) than in patients having a 'neoappendicostomy' (two of four). Because so few patients had a 'neoappendicostomy' no explanation can be given for this difference. However, one must expect more complications, especially stenoses, in patients having a 'neoappendicostomy' since the stoma is not created from a natural luminal organ.

The most common complication was stenosis of the appendix occurring in four of 16 patients; however, this only caused one patient to discontinue use of the stoma. The frequency of stenosis is in accordance with several previous studies[2,3,6] and lower than in another[8]. The occurrence of stenoses may be reduced by instructing patients to insert a catheter through the stoma once or twice every day, even if they only use it for wash-outs every second day[2]. Also, the frequency of stenoses may be reduced by decreasing the number of superficial infections around the stoma and by ensuring that the flaps used for the creation of the V-Y plasty are well vascularized.

Most failures occurred within a few months after the operation and were caused by pain during wash-outs. The number of patients experiencing abdominal discomfort during wash-out was higher than in previous studies. This could be because a larger volume of water was used by the present patients than was used in the only other study of this procedure in adult patients[6].

The mean time required for the enema was 30 min each or every other day. This is in accordance with previous studies[1–3] and less than in another study[6]. As in previous studies[1,2,4,7], the frequency of wash-outs and the volume of water used in each individual patient was determined by trial and error during the first months after the operation. Therefore, it is most important that all patients are well motivated and understand that some time is necessary to learn the procedure. During this initial period, instructions from an experienced nurse with a special interest in this field are very important.

Since this is a minor and reversible operation, it could often be indicated in selected patients with severe constipation or faecal incontinence resistant to other therapies. However, larger studies are needed for further evaluation, and long-term results have yet to be described.

Glutaraldehyde cross-linked collagen in the treatment of faecal incontinence

D. KUMAR, M. J. BENSON and J. E. BLAND

Department of Surgery and Gastrointestinal Motility Unit, St George's Hospital, Blackshaw Road, London SW17 0QT, UK
Correspondence to: Dr D. Kumar

Background The treatment of faecal incontinence secondary to internal anal sphincter dysfunction is unsatisfactory. The aim of the study was to evaluate the efficacy of anal glutaraldehyde cross-linked (GAX) collagen injections in patients with a surgically incorrectable disorder.

Methods Seventeen patients were studied: nine had idiopathic faecal incontinence, three had incontinence following haemorrhoidectomy, two following internal sphincterotomy, two following an internal sphincter defect from obstetric injury and one following treatment for fistula *in ano*. All patients were refractory to conservative treatment and were unsuitable for surgical repair. All had anorectal physiology and endoanal ultrasonography before and after GAX collagen injections.

Results All patients tolerated the injection without side-effects. All patients had an intact external anal sphincter. Following injection, 11 patients showed marked symptomatic improvement. One patient reported symptomatic improvement but remained in clinical grade 3, and two reported minimal improvement. There was no improvement in three patients, but one of these had a repeat injection and showed significant improvement subsequently.

Conclusion Injection of GAX collagen in the anal canal is a simple and well tolerated method of treating faecal incontinence due to internal sphincter dysfunction. Early results suggest it provides an easy and reliable alternative to the currently available methods that are often unsuccessful and at best unpredictable.

The aetiology of faecal incontinence is varied and includes obstetric damage to the anal sphincters, neuropathy of the sphincter muscles and the pelvic floor muscles, and iatrogenic damage to the internal and external anal sphincters during procedures such as lateral internal sphincterotomy and haemorrhoidectomy[1,2].

Repair of the external anal sphincter following obstetric and direct trauma yields good results in 70–90 per cent of patients[3,4]. Associated neuropathy yields less favourable results[4,5]. Results of surgical reconstruction of the internal anal sphincter are even less promising. Conservative treatment, although effective in some patients, is unsuccessful in the majority.

Variation in radial canal pressures has been described previously[6]. This may reflect anatomical deficiency or weakness of the sphincter muscle in a defined quadrant. Endosonographic studies of the anal canal have shown morphological asymmetry of the internal anal sphincter in patients with faecal incontinence[1].

Patients with a fissure *in ano* refractory to medical management undergo lateral internal sphincterotomy. Approximately 10 per cent of these patients develop faecal leakage or incontinence to flatus. This group often has a gutter deformity in the anal canal, which is thought to be responsible for the seepage of faecal material[7].

The use of an injectable bulk enhancing agent to increase urethral resistance at the level of the bladder neck has been tried in patients with urinary incontinence with considerable success[8]. Glutaraldehyde cross-linked (GAX) collagen, a highly purified bovine dermal collagen, has been developed for use as a periurethral bulking agent. It is biocompatable and does not begin to degrade for approximately 12 weeks after the injection. The persistence of GAX collagen has been verified histologically 9–19 months after injection[9,10]. An allergic response occurs in up to 3 per cent of patients, and subclinical seropositivity has been reported with no adverse effect[11,12].

The use of an injectable bulk-enhancing agent in the anal canal in patients with faecal incontinence has not been tested. The aim of this study was to evaluate the efficacy of anal GAX collagen injections for the treatment of idiopathic faecal incontinence in patients who have failed conservative treatment and have a surgically incorrectable problem.

Patients and methods

Seventeen patients (five men, 12 women), aged 42–76 (mean 53) years, were recruited to the study. Nine patients had idiopathic faecal incontinence secondary to weakness of the internal anal sphincter. Three patients were incontinent following haemorrhoidectomy, two following an internal sphincterotomy, two had an internal sphincter defect following obstetric injury, and one following surgical treatment for fistula *in ano*. All patients had grade 2 or 3 faecal incontinence (incontinent to flatus and liquid stool). All patients complained of faecal leakage and soiling of underwear, had failed conservative treatment and had a surgically incorrectable problem.

All patients had anorectal physiology and endoanal ultrasonography performed before GAX collagen injections. Basal and squeeze pressures were measured before and after injection using a water-filled microballoon manometry system. Rectal volume sensation at the threshold, constant volume and maximum tolerable volume was also measured.

An intradermal test injection (0·2 ml) was given to all patients before injection of GAX collagen in the anal canal. The test result was read 1 month later and the therapeutic injection given if there was no allergic response.

The injections were performed in the left lateral position using a proctoscope, preloaded GAX collagen syringe and a Gabriel haemorrhoid injection needle. The presence of a gutter deformity or asymmetry in the anal canal was sought and

Paper accepted 12 December 1997

collagen was injected submucosally either until the gutter deformity was corrected or adequate symmetrical anal cushions were raised. The injection was given in one to three positions in all patients. A maximum of 2 ml collagen was injected in one session.

Clinical outcome was measured at an interview with the patient on follow-up visits at 1 and 6 months. Continence grading after injection was established in all patients along with the frequency of incontinence episodes following the injection.

Results

All patients tolerated the injection without any ill-effects. Eleven patients showed marked symptomatic improvement. None of these leaked liquid stool or reported soiling. One patient reported symptomatic improvement, but remained in clinical grade 3 although the frequency of incontinence episodes improved, and two others reported minimal improvement. Three patients reported no improvement, but one had a repeat injection and showed significant improvement. Three patients have required repeat injections. The mean follow-up is 8 (range 4–12) months.

Anorectal physiology and endoanal ultrasonography

All patients had an intact external anal sphincter on endoanal ultrasonography. Mean resting pressures were low before operation (mean(s.e.m.) 30(11) cmH_2O) and remained low after operation (45(10) cmH_2O). Although there was a trend towards an increase in resting pressures, the differences were not significant. Similarly, squeeze pressures were not significantly different before (125(20) cmH_2O) and after (130(10) cmH_2O) injection. Rectal volume sensation was also not affected significantly by GAX collagen injections.

Discussion

Anal collagen injection is a simple procedure which can be performed easily in the outpatient department and is well tolerated and free of complications. Despite its simplicity, there is a learning curve in recognizing the area where the injections should be given.

In this study the majority of patients reported significant symptomatic improvement. In some where there was little or no initial improvement, a repeat injection provided significant symptomatic benefit. This appears to be a major advantage of this technique in that repeat injections can be given to fill keyhole deformities or raise anal cushions until the continence grade improves.

Although there was some improvement in resting and squeeze pressures after injection, this did not reach statistical significance. This is not surprising, because physiological measurements do not necessarily correlate with symptoms and low resting and squeeze pressures are fully compatable with normal continence.

Faecal incontinence as a result of trauma to the internal sphincter, either during fistula surgery or controlled division of the internal sphincter during lateral internal sphincterotomy, is associated with impairment of continence in up to 10 per cent of patients. Results of surgical reconstruction in such patients are disappointing. A flap advancement technique into the anal canal to fill the gutter or keyhole deformity following lateral sphincterotomy has been described recently[7]. Although the initial results are encouraging, it has a limited place in the management of faecal incontinence for a wide range of reasons. Even in patients in whom advancement flaps may be helpful, an initial trial with collagen to fill the deformity may be worthwhile, as seen in three patients in this study. Another possible role for GAX collagen injections is in patients with a combined internal and external sphincter defect. Combination therapy with GAX collagen and repair of the external sphincter may provide better results than repair of the external sphincter alone.

The mechanism by which collagen injection works is uncertain. It seems likely that it is purely a mechanical effect of either filling a gutter deformity or raising cushions to keep the anal canal closed, thus preventing faecal leakage. Alternatively it may provide an adequate anal lining which is bulky enough to plug the anal orifice while the internal anal sphincter contracts tonically.

Initial results from this study suggest that GAX collagen injections are a simple way of treating faecal leakage and incontinence with impairment of internal anal sphincter function or internal anal sphincter defects.

Functional results following the antegrade continence enema procedure

K. R. SHANKAR, P. D. LOSTY, S. E. KENNY, J. M. BOOTH, R. R. TURNOCK,
G. L. LAMONT, R. J. RINTALA and D. A. LLOYD

Department of Paediatric Surgery, Institute of Child Health, Alder Hey Children's Hospital, University of Liverpool, Liverpool, UK
Correspondence to: Mr P. D. Losty, Institute of Child Health, Alder Hey Children's Hospital, Eaton Road, Liverpool L12 2AP, UK

Background Forty children who underwent the antegrade continence enema (ACE) procedure for faecal soiling were studied to determine factors predictive of outcome.

Methods There were four patient groups: (1) ambulant with spinal dysraphism ($n = 13$), (2) wheelchair bound with spinal dysraphism ($n = 14$), (3) ambulant with miscellaneous disorders ($n = 11$) and (4) wheelchair bound with miscellaneous disorders ($n = 2$). Effectiveness of the procedure was assessed using technical evaluation and quality-of-life improvement (QOLI) scores (0–5). Objective assessment included colonic transit time (CTT) and anorectal manometry. Median follow-up was 21 (range 5–37) months.

Results Some 28 of 40 children achieved continence. The procedure was reversed in four of 40 children. Of the other 36 children with a functioning ACE stoma, all reported improvement in quality of life (mean QOLI score 3·5). There were no significant differences in technical evaluation score, QOLI score, CTT, manometry findings or continence between ambulant groups and the wheelchair-bound group with miscellaneous disorders. QOLI score, anorectal squeeze pressure and continence were significantly poorer in those who were wheelchair bound with spinal dysraphism. Absent squeeze pressure was associated with poor outcome.

Conclusion Wheelchair-bound children with spinal neuropathy have a poorer outcome following the ACE procedure. Although ACE is an effective method of promoting faecal continence, it is essential to determine the aetiology of incontinence and sphincter function before operation.

Faecal incontinence is a physically, emotionally and psychologically disabling symptom, predisposed by a variety of congenital and acquired disorders in childhood. These disorders notably include spina bifida, allied spinal neuropathies, anorectal malformations, Hirschsprung's disease and hypoganglionosis, and, rarely, may follow anorectal sphincter trauma. Historically, incontinence in such children has been managed by means of dietary manipulation, laxatives, suppositories and rectal enemas[1]. While these measures suffice in some cases, a significant proportion of paediatric patients remains incontinent. The introduction of the antegrade continence enema (ACE) procedure has been a major advance[2]. Proponents of the ACE operation report excellent control of faecal continence[2–6]. The aim of this study was to evaluate functional results following the ACE procedure in an effort to help identify factors predictive of outcome.

Patients and methods

All children with faecal incontinence undergoing the ACE procedure between November 1993 and July 1996 were included in the study. Before surgery all children had tried non-operative management with laxatives, suppositories, enemas, manual evacuation and high rectal washouts. A consultant paediatric surgeon and a stoma nurse specialist counselled patients and their families before the ACE procedure. Patients were categorized into four groups according to diagnosis and mobility: (1) ambulant with spinal dysraphism, (2) wheelchair bound with spinal dysraphism, (3) ambulant with miscellaneous disorders and (4) wheelchair bound with miscellaneous disorders.

Operative technique

All patients had routine bowel preparation. Prophylactic antibiotics (cefotaxime and metronidazole) were administered at the time of surgery. In the early part of the study the appendix was reimplanted orthotopically into the caecum with a submucosal tunnel to ensure that it was non-refluxing[2]. Subsequently, the approach was modified to simple appendicostomy, imbricating the caecum around the base of the appendix with interrupted sutures[3]. A skin flap was routinely fashioned at the appendicocutaneous junction to create a wide cutaneous stoma which could be catheterized easily. Tubularized caecum (lateral caecal flap) was employed in children whose appendix had been removed or used in a urological procedure[10]. After operation the stoma was left intubated to 'mature' for 2 weeks using a lubricated Silastic (Dow Corning, Reading, UK) Foley 10–12-Fr catheter[2,4].

Functional assessment

The effectiveness of the procedure was evaluated subjectively using a technical evaluation score and a 'quality of life' improvement (QOLI) score[1,5]. These scores were determined from a questionnaire completed by patients and their parents. The technical score (0–20, where 20 represented the best possible score) addressed the following: (1) degree of postoperative soiling, (2) speed of self-catheterization and (3) time taken to complete the ACE washout. The QOLI score sought to ascertain the child's perception of the effectiveness of the ACE procedure in preventing soiling. Briefly, a score of 5 was ideal or perfect, 4 denoted great improvement but still some problems, 3 was definite improvement but not perfect, 2 showed some improvement, 1 indicated little improvement and 0 was no

---

Paper accepted 23 November 1997

improvement. Continence was defined as less than one episode of soiling per month and 'clean' within 60 min after the ACE washout.

Colonic transit time (CTT) was measured by ingestion of ten radio-opaque marker beads daily with breakfast for six consecutive days. A single plain abdominal radiograph was taken on day 7. CTT was calculated in days by determining the number of markers (M) counted on the radiograph using the formula[7]: CTT = M/10.

Anorectal manometry was performed using a multichannel catheter system (Synectics Medical, Enfield, UK). An open fluid perfusion system was utilized and pressure measured by transducers housed in the perfusion line, in turn connected to a PC Polygraph HR preamplifier (Synectics Medical). An analog–digital converter and personal computer were used to convert the signal to digital values. This permitted measurement of the anorectal resting pressure, squeeze pressure and anorectal reflex[8,9].

Statistical analysis

Data were analysed using SPSS for Windows (v.6. 1.2; SPSS, Chicago, Illinois, USA) and GraphPad Prism (GraphPad Software, San Diego, California, USA). Independent-samples t test with F test for homogeneity of variance and the χ^2 test were used as appropriate. $P < 0{\cdot}05$ was considered significant.

Results

During the study 40 patients (22 girls, 18 boys) underwent the ACE procedure. The causes of faecal incontinence are shown in *Table 1*. Median age at operation was 11 (range 6–21) years. Median duration of follow-up was 21 (range 5–37) months. A completed patient and parent questionnaire was obtained for all children. Six patients declined to undergo estimation of CTT and anorectal manometry studies.

Surgical complications

Five patients had minor wound infections after operation that responded to antibiotic therapy. Eighteen children developed stomal stenosis, seven of whom responded to repeated dilatation. Eleven patients needed formal surgical correction using a V–Y plasty. All patients who had the appendix reimplanted and five of seven of those who had a tubularized caecal flap developed stomal stenosis ($P = 0{\cdot}001$ *versus* simple appendicostomy). Two patients had formal reimbrication of the appendicocaecal junction in an effort to reduce leakage of faeces. Caecal perforation resulting in abdominal pain and peritonitis was encountered in a child following false passage of a catheter. This was explored and repaired surgically. Faecal fistula developed in a further patient who is presently undergoing a trial of non-operative management. Finally, an appendicostomy was converted to a tubularized caecal flap in a child whose abdomen was explored to relieve postoperative adhesion obstruction.

Functional outcome

The ACE procedure was reversed in four children (three had spina bifida, two of whom were wheelchair bound; one had a failed revisional posterior sagittal anorectoplasty) within 5–19 months because of uncontrollable faecal soiling following operation (*Table 2*). Three of these patients now have a permanent colostomy and the other reverted to a regimen of rectal enemas and manual evacuation. These patients did not participate in the functional study. Eight further patients, five who were wheelchair bound with spinal dysraphism, two who were ambulant with myelomeningocele and one who was ambulant with tethered cord and lipomeningocele, were classed as incontinent following the ACE procedure, giving an overall success rate of 28 of 40 children. The mean QOLI score was 3·5 and all children remaining with an ACE stoma reported some improvement in quality of life. QOLI scores were significantly lower in the group of patients with spinal dysraphism who were wheelchair bound than in all other groups ($P = 0{\cdot}033$, t test); there were no significant differences between the two groups of ambulant patients and the wheelchair-bound group with miscellaneous disorders. Only seven of 14 patients who were wheelchair bound with spinal dysraphism were continent following the ACE procedure, compared with 21 of the other 26 patients ($P = 0{\cdot}016$, t test).

Maximal anorectal squeeze pressure was significantly lower in the patients with spinal dysraphism who were wheelchair bound than in all other groups ($P = 0{\cdot}0006$) (*Table 2*). Overall, in this series seven of eight children classified as incontinent after operation had no anorectal squeeze pressure ($P = 0{\cdot}0014$ *versus* all other continent patients ($n = 28$), χ^2 test).

There were no differences in CTT or technical evaluation scores between patient groups or when children were classified according to functional outcome. There were no significant differences in technical evaluation score, QOLI score and continence rates when patients were analysed according to the nature of the surgical procedure performed (*Table 3*).

Enema technique

The majority of the children administer the ACE enema on alternate days. In 22 patients a phosphate enema followed by a saline washout has proved satisfactory. Judicious use of liquorice stick with saline, saline alone, Microlax (Evans Medical, Leatherhead, UK) and Picolax

Table 3 Comparison between different surgical techniques

Surgical technique	No. of patients	Technical evaluation score*	QOLI score*	Continent
Appendicostomy	23	16 (11–20)	3 (1–3)	17
Tubularized caecal flap	7	13 (9–16)	2 (1–4)	5
Orthotopic reimplantation of appendix	6	15 (12–19)	2 (2–4)	6

*Values are median (range). QOLI, quality of life improvement

(Ferring, Feltham, UK) is useful in five patients who have developed adverse reactions to phosphate. Two patients who experienced abdominal cramps following the enema responded adequately to the use of proprietary antispasmodic (Buscopan; Boehringer Ingelheim, Bracknell, UK) and motility (Lomotil; Searle, High Wycombe, UK) agents.

Discussion

Faecal incontinence in a child is a significant psychosocial handicap. Previously there were few options available when standard techniques of dietary manipulation, laxatives and enemas failed. Many of these children were condemned either to a lifetime of faecal incontinence and pads or to faecal diversion with a colostomy. In 1990, Malone *et al.*[2] pioneered the ACE procedure. The rationale behind this operation is simple: 'to provide patients with a continent catheterisable colonic stoma' so that they can remain clean and independent[2]. The ACE operation has now been offered to a variety of patients with faecal incontinence, and proponents report excellent control of the incontinence[2–6].

In the present study early failure (persistent faecal incontinence) occurred in four of 40 patients, prompting critical appraisal of the authors' institutional experience with the ACE procedure. Three of these patients had spina bifida, two of whom were confined to wheelchairs; the other patient had a revisional posterior sagittal anorectoplasty. Further analysis revealed a significantly poor functional outcome for wheelchair-bound patients with spinal dysraphism. Only seven of 14 of these children derived benefit (i.e. are rendered clean) from an ACE operation. The reasons for failure were apparent on scrutinizing the anorectal manometry profiles of these patients. Overall, maximum anorectal squeeze pressures were significantly lower in the wheelchair-bound patients with spinal dysraphism, and in seven of eight of these children who were incontinent following the ACE operation no squeeze pressure could be recorded. This led to persistent and involuntary episodes of faecal soiling despite numerous efforts to adjust or tailor enema schedules to individual needs. Of interest was the fact that seven of these patients who did have an element of squeeze pressure activity could be made clean. Three other patients remained incontinent by the reported criteria, although one had an improved QOLI score. All of these children had some form of spinal dysraphism: two were ambulant with myelomeningocele and no squeeze pressure, and one was ambulant with lipomeningocele and tethered cord.

Surgical complications were not infrequent. Stomal stenosis occasionally responded to dilatation, although 11 of 18 affected patients required a V–Y plastic revision. These problems were significant in children who had orthotopic reimplantation or a tubularized caecal flap[2,10] and are less frequent now that appendicostomy with caecal imbrication is performed[3,4]. A button caecostomy device is a new alternative[12]. Children and their parents must be given instructions on signs and symptoms that herald viscus perforation and enema toxicity[11]. Close communication between the patient, parents, nurses and surgical staff reinforces these issues.

The ACE operation in selected patients may have a 70 per cent success rate in achieving faecal continence. Caution should be exercised when offering this procedure to patients who are wheelchair bound with spinal dysraphism who, at best, achieve a 50 per cent continence rate. Absent anorectal squeeze pressure is a poor prognostic indicator.

Laparoscopy in the management of the impalpable undescended testis

Background This study evaluates the role of laparoscopy for managing the intra-abdominal testis.

Methods Over 30 months, 48 children (six with previous groin explorations) underwent laparoscopy for a unilateral impalpable undescended testis. The patients' age ranged from 1 to 9 years.

Results Eleven children required insertion of 'working ports' for mobilization of obscuring colon before the diagnosis could be established. Twenty-eight children had an absent testis. In nine, vas and vessels entered the internal ring. In 19, vas and vessels ended blindly above the internal ring. Twenty children had an intra-abdominal testis. Ten underwent a laparoscopic single-stage orchidopexy (eight without and two with ligation of vessels); at a minimum follow-up of 2 years, one testis in this group had atrophied, three were located in the lower half of the scrotum and six in the upper half. The remaining ten children underwent a laparoscopic two-stage Fowler–Stephens operation. At a minimum follow-up of 6 months, eight of these testes were palpable in the lower half and two in the upper half of the scrotum.

Conclusion In the majority of cases, laparoscopy obviates the need for groin exploration. Technically a first-stage Fowler–Stephens procedure can be performed easily and effectively via the laparoscope. However, the second-stage Fowler–Stephens procedure or single-stage orchidopexy requires laparoscopic skills and may not necessarily provide sufficient length to the testicular attachment.

Cryptorchidism affects 0·8 per cent of male children at 1 year of age[1]. In approximately 20 per cent of these children the testis will be impalpable and presumed to be located within the abdominal cavity[1,2]. Although ultrasonography, computed tomography and venography have been used[3], laparoscopy is the most reliable method of confirming the presence of an intra-abdominal testis[4–10]. Following localization of an intra-abdominal testis an open procedure, one-stage orchidopexy, one- or two-stage Fowler–Stephens procedure or microvascular transfer, is required for placement of the testis within the scrotum[11]. Alternatively the testis is removed.

Therapeutic laparoscopy is beginning to be used in the management of intra-abdominal testes[9,10,12–16]. This report describes present experience in assessing the role of laparoscopic surgery in the management of the impalpable undescended testis.

Patients and methods

Over 30 months, 48 children underwent laparoscopy for evaluation of a unilateral impalpable testis following careful palpation of the scrotum and groin under general anaesthesia. Six of the patients had undergone a negative groin exploration at other institutions. The mean age of the patients was 3·3 (range 1–9) years. Informed consent was obtained for laparoscopy with permission to proceed with orchidectomy, one- or two-stage orchidopexy or groin exploration depending on the findings at laparoscopy.

Under general anaesthesia the abdomen was palpated to ensure that the bladder was empty. A primary periumbilical port (3·5–10 mm) was inserted using an open technique[17] and a pneumoperitoneum created using carbon dioxide with a flow rate of 0·2 l/min and an intra-abdominal pressure of 6–8 mmHg. Following exploration of the abdominal cavity in a Trendelenberg position, with or without a lateral tilt, the sites (usually high iliac/low lumbar region and suprapubic/opposite iliac region) and sizes (3·5–10 mm) of one or two working ports were selected depending on the child's size, laparoscopic findings and the type of procedure required.

When the testis was low with a reasonably long vascular pedicle, single-stage orchidopexy was attempted with complete mobilization of the testicular attachment from the lower pole of the kidney to the base of the bladder. The mobilized testis was then placed through the inguinal canal and secured in a dartos pouch with or without groin incision. Following early experience with this technique, single-stage orchidopexy was converted to a one-stage Fowler–Stephens procedure (division of testicular vessels and orchidopexy at the same time) when the vascular pedicle was too short to allow testicular positioning in the lower half of the scrotum.

In children undergoing a two-stage Fowler–Stephens procedure a first stage (division of testicular vessels) was performed with laparoscopic ligation of the testicular vessels using two metal clips or non-absorbable suture ligatures. Subsequently a lararoscopic second-stage procedure (mobilization of testis and orchidopexy) was done 6–9 months later.

Results

Following initial laparoscopy, 11 children required insertion of one or two working ports for mobilization of the colon or division of adhesions to establish the diagnosis. Twenty-eight children had an absent testis on the side under investigation. In 19, the vas and vessels were seen to end blindly above the internal ring. In the remaining nine, vas and vessels entered the inguinal canal and groin exploration was performed. Histological evaluation of tissue excised from the end of the attenuated spermatic cord confirmed the presence of the vas deferens but did not identify any testicular tissue.

Presented in part to the British Association of Paediatric Surgeons XLII annual International Congress in Sheffield, UK, July, 1995
Paper accepted 12 December 1997

Twenty children had an intra-abdominal testis. Of these, ten underwent a single-stage laparoscopic orchidopexy (eight without and two with division of the testicular vessels). At follow-up (mean 2·5 (range 2–4) years), three testes were located in the lower half of the scrotum and six in the upper half. One high testis managed by extensive mobilization with division of the testicular vessels had atrophied. The remaining ten children underwent a laparoscopic two-stage Fowler–Stephens procedure and at subsequent follow-up (mean 1·5 (range 0·5–3·5) years) eight testes were located in the lower half and two in the upper half of the scrotum.

The mean operating time was 18 (range 15–40) min for laparoscopy alone, 30 (range 22–60) min for a first-stage Fowler–Stephens procedure and 65 (range 52–90) min for single-stage orchidopexy and second-stage Fowler–Stephens operation. All children who had laparoscopy alone or a first-stage Fowler–Stephens procedure were managed as day cases. Children undergoing orchidopexy either as single-stage procedure or second-stage Fowler–Stephens operation stayed in hospital overnight but none required opiate analgesia. There were no technical failures and no laparoscopy-related complications.

Discussion

The risks of atrophic change and malignancy developing within an undescended testis are widely recognized[18,19], as is the role of laparoscopy in identification of the intra-abdominal testis[4–10]. It has been reported that single-port diagnostic laparoscopy fails to obtain the correct diagnosis in 5–8 per cent as a result of bowel or adhesions obscuring the testis or its attachments[7,8,20]. Laparoscopic examination should include complete visualization of the pelvis and retroperitoneum behind the colon. It is therefore not surprising that in this series a high proportion of children (11 of 48) required insertion of one or two additional laparoscopic ports. In the six children who had previous groin exploration elsewhere, laparoscopy demonstrated that the testis was absent in four and in two it was located within the abdominal cavity. Diagnostic laparoscopy should be 100 per cent accurate in the hands of an experienced laparoscopic surgeon. The value of groin exploration when vas and vessels enter the inguinal canal in the absence of a palpable testis is uncertain as testicular tissue is rarely found.

Operative laparoscopy is becoming increasingly common and recent reports of orchidopexy and first-stage Fowler–Stephens operation suggest that the technique may be used as an alternative to open surgery for definitive management of the intra-abdominal testis[9,10,12–16]. The present experience supports that of Nassar[12] and suggests that a first-stage Fowler–Stephens orchidopexy can effectively be performed via the laparoscope. The technique, however, requires three laparoscopic ports.

Single-stage orchidopexy and second-stage Fowler–Stephens procedures are conventionally carried out via a groin incision. Using a laparoscopic approach, the mobilized testis can be pulled into the scrotum via the incision used to create a dartos pouch[21]. This technique requires extensive laparoscopic experience. The role of single-stage laparoscopic orchidopexy remains uncertain as even following extensive mobilization it is frequently not possible to gain sufficient length of vascular pedicle to ensure that the testis remains located in the lower half of the scrotum. This was less of a problem in children undergoing a Fowler–Stephens orchidopexy.

Laparoscopic orchidectomy is seldom necessary[9,10,14,22]; it was not required in any of the children in this series. However, if orchidopexy is considered unsuitable, laparoscopic orchidectomy can be done.

In this study the success of laparoscopic orchidopexy for intra-abdominal testes as judged by placement of the testis within the scrotal sac was high (19 of 20 testes). This compares well with the results of open surgical techniques: 67 per cent for one-stage Fowler–Stephens, 77 per cent for staged Fowler–Stephens, 81 per cent for intra-abdominal orchidopexy and 84 per cent for microvascular transfer[11].

Stimulation of inflammatory markers after blunt trauma

P. V. GIANNOUDIS*, R. M. SMITH*, R. E. BANKS†, A. C. J. WINDSOR‡,
R. A. DICKSON* and P. J. GUILLOU‡

*Departments of *Trauma and Orthopaedics, †Cancer Medicine, and ‡Surgery, St James's University Hospital, Beckett Street, Leeds LS9 7TF, UK*
Correspondence to: Mr R. M. Smith

Background Inflammatory mediators are released after trauma and may be related to the pathogenesis of sepsis. A prospective combined study of the pattern of release of an inflammatory mediator, interleukin (IL) 6, leucocyte activation (polymorphonuclear leucocyte (PMN) CD11b receptor expression and plasma elastase-α_1 proteinase inhibitor complex (E–α_1PI)) and soluble endothelial adhesion molecule expression (soluble E-selectin (sE-selectin) and soluble intracellular adhesion molecule 1 (sICAM-1)) was performed in patients suffering blunt trauma without adult respiratory distress syndrome (ARDS) or multiple organ failure syndrome (MOFS).

Methods Thirty-one patients with a mean Injury Severity Score (ISS) of 14 (range 9–57) were studied. Venous blood samples were collected within 6 h of injury and then at 1, 3, 5 and 7 days. Leucocyte CD11b expression was quantified by flow cytometry. Serum IL-6, plasma E–α_1PI, sE-selectin and sICAM-1 were measured by enzyme-linked immunosorbent assay.

Results Serum IL-6, CD11b expression and E–α_1PI levels were significantly raised above control values ($P<0{\cdot}0001$) on admission, slowly returning towards control values over the study period (median IL-6, 140 pg/ml *versus* undetectable; CD11b, 14·8 *versus* 6·4 mean channel fluorescence units; E–α_1 PI, 208 *versus* 52 μg/l). The sICAM-1 level rose to a median of 539 ng/ml at 5 days (control 243 ng/ml). The median sE-selectin level also progressively increased to a maximum level of 80 ng/ml at 5 days (control 49 ng/ml). Eleven patients developed postoperative sepsis. Significant differences in CD11b expression were seen at days 3, 5 and 7 and in E–α_1 PI at 6 h, 24 h and 3 days in patients who subsequently developed sepsis ($P<0{\cdot}05$). Severe injury (ISS 16 or greater) was associated with significantly greater responses in these measurements.

Conclusion These data show that markers of inflammation are specifically stimulated by trauma even when ARDS and MOFS do not occur. The CD11b receptor on PMNs may be useful in screening patients destined to develop post-traumatic sepsis.

Multiple organ failure syndrome (MOFS) is a leading cause of death in patients after multiple trauma. This has been associated with an exaggerated systemic inflammatory response syndrome which may occur after trauma and may lead to critical organ injury[1]. Several components of the immune system have been implicated in this process including the release of proinflammatory cytokines, activated polymorphonuclear leucocytes (PMNs) and leucocyte–endothelial interactions[2]. The role of each of these elements is not clear although many consider the neutrophil as the pivotal player in the pathogenesis of adult respiratory distress syndrome (ARDS) and MOFS and the expression of cell surface receptors on neutrophils to be regulated by proinflammatory cytokines[3–9]. However, a specific inflammatory marker has not yet been implicated in the process underlying the development of MOFS.

The proinflammatory cytokine interleukin (IL) 6 is produced by a variety of cells such as monocytes, macrophages, lymphocytes, fibroblasts and endothelial cells[10,11]. IL-6 is involved in the modulation of local inflammation and the systemic reaction known as the acute-phase response which is characterized by fever, leucocytosis, tachycardia, net catabolism and alteration in the production of hepatic proteins[12].

Activated leucocytes express surface glycoproteins known as integrins, of which the β_2 integrins are particularly important[13]. These consist of a β_2 (CD18) chain covalently linked to one of three different α chains (CD11a, CD11b, CD11c). The CD11b/CD18 receptor binds complement and has a major role in neutrophil adhesion and diapedesis[14]. PMN–endothelial cell adhesion involves intracellular adhesion molecule (ICAM)1 and E-selectin[15,16], the E-selectin initiating and ICAM-1 completing the adhesion process which allows migration of the neutrophils across the vascular endothelium[17], where final tissue destruction involves the release of elastase from PMNs[18]. Elastase degrades elastin, collagen, proteoglycans and fibronectin[19] and measurement of complexed neutrophil elastase provides a sensitive indicator of neutrophil activation.

The purpose of this investigation was to study changes which occur in serum IL-6, plasma elastase–α_1 proteinase inhibitor complex (E–α_1PI), neutrophil CD11b receptor expression, serum soluble ICAM-1 (sICAM-1) and soluble E-selectin (sE-selectin) levels to determine the relationship between these aspects of the inflammatory process in a series of patients suffering blunt orthopaedic trauma, who did not develop ARDS or MOFS but did develop sepsis.

Fractured tibia*	7	9 (9–10)	1
Fractured forearm*	1	11	1

*Other injuries sustained. ISS, Injury Severity Score

Patients and methods

Thirty-one adult patients were studied prospectively following blunt trauma. All patients arrived in hospital within 6 h of injury, had an Injury Severity Score (ISS) of 9 or more and were subsequently in hospital for at least 7 days. *Table 1* shows the patients' characteristics and the injuries sustained with the corresponding ISS. For comparison the patients were divided into two groups: a severely injured group with an ISS of 16 or more, and a group with moderate injury and an ISS of 9–15, as defined by Ertel *et al.*[20]. Patients were defined as developing sepsis if a systemic response to infection was clinically evident (i.e. two or more of the following: peripheral white blood cell count of less than 2×10^9 per litre or more than 15×10^9 per litre; temperature higher than 38°C; twofold increase in serum alkaline phosphatase level; bilirubin level higher than 20 μmol/l; hypotension, with systolic blood pressure less than 100 mmHg for 2 h; and tachycardia greater than 100 beats per min for 2 h), along with a clinical evidence of an infection site supported by a positive bacterial culture[21]. Ethics committee approval was obtained and all patients or their representatives gave oral or written consent.

Venous blood samples were collected on arrival in the emergency department and at 1, 3, 5 and 7 days following injury. Similarly, venous blood samples were collected from 20 (11 women and nine men) healthy uninjured individuals, with a median age of 54 (range 23–85) years who formed the control group for this study. The serial venous blood samples were collected on ice into two types of endotoxin-free vacutainer tubes, one containing ethylenediamine tetra-acetic acid (EDTA) and one containing clot activator. Processing took place within 2 h of collection. The tubes containing the clot activator were centrifuged at 1000 r.p.m. (MSE; Scientific Instruments, Crawley, UK) for a period of 10 min, the serum and plasma were collected and stored at −70°C. Flow cytometric studies were performed on 100 μl blood from the EDTA tube.

Flow cytometry of polymorphonuclear leucocytes

Polymorphonuclear cells were stained with fluorescent labelled antibodies against CD11b in a whole blood assay as described previously[22]. An isotype-matched fluorescein isothiocyanate-conjugated monoclonal antibody that does not specifically react with human cells was used as a negative control to exclude any non-specific Fc-related antibody binding.

Immunofluorescence was determined on a Coulter Epics (Luton, UK) flow cytometer. Forward angle and 90° light scatter measurements were collected. At least 10 000 events were counted on each sample within a region gated for PMNs. The data were analysed using the Coulter Epics XL cytometer software and expressed in mean channel fluorescence units.

Determination of inflammatory markers

Serum IL-6, s-ICAM and sE-selectin levels were measured using enzyme-linked immunosorbent assay (ELISA) kits (R and D Systems, Minneapolis, Minnesota, USA). All measurements were performed in duplicate. Plasma E-α_1 PI levels were determined using an indirect sandwich ELISA assay[23] recalibrated against the currently commercially available Merck elastase assay.

Statistical analysis

Non-parametric tests (Mann–Whitney *U* test) were used to assess differences between observed values, and area under the curve (AUC). Differences were considered significant at $P < 0{\cdot}05$.

Results

Serum IL-6, plasma E-α_1PI levels and CD11b expression in patients were significantly raised above control levels ($P < 0{\cdot}0001$) on admission slowly returning towards control values over the study period (*Figs 1*, *2* and *3*). The sICAM-1 and sE-selectin levels were slightly raised initially and increased with time. This rise was initially not significantly above control values but became significant after day 3.

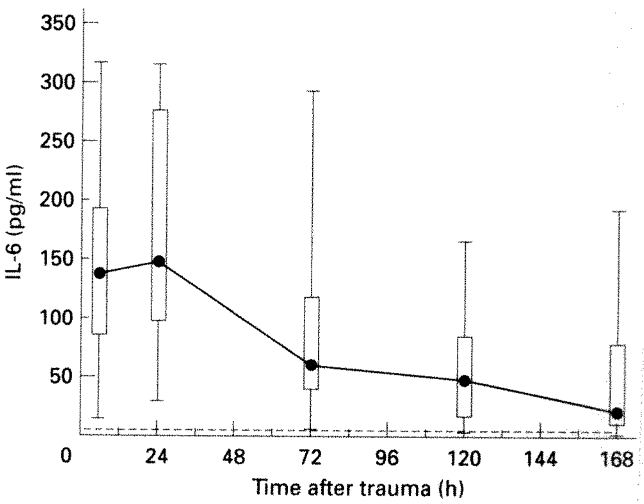

Fig. 1 Interleukin (IL) 6 concentrations with time following trauma ($n = 31$). Median values (dots), interquartile ranges (boxes), and the maximum and minimum values (bars) are shown. The 95 per cent cut-off for the control group is represented by the dotted line

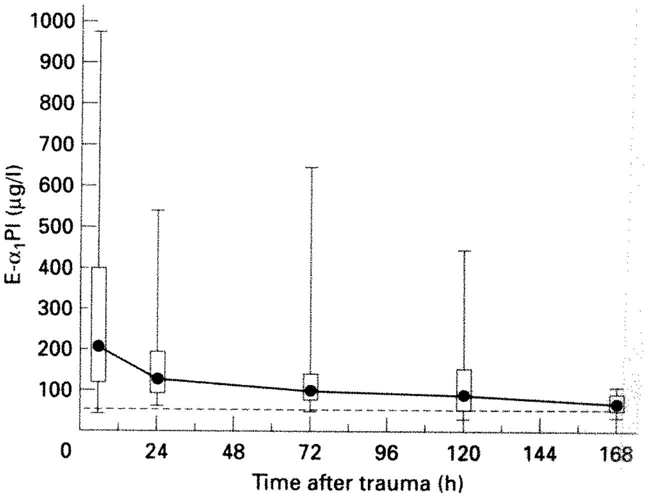

Fig. 2 Elastase –α_1 proteinase inhibitor (E–α_1 PI) concentrations with time following trauma ($n = 31$). Median values (dots), interquartile ranges (boxes), and the maximum and minimum values (bars) are shown. The 95 per cent cut-off for the control group is represented by the dotted line

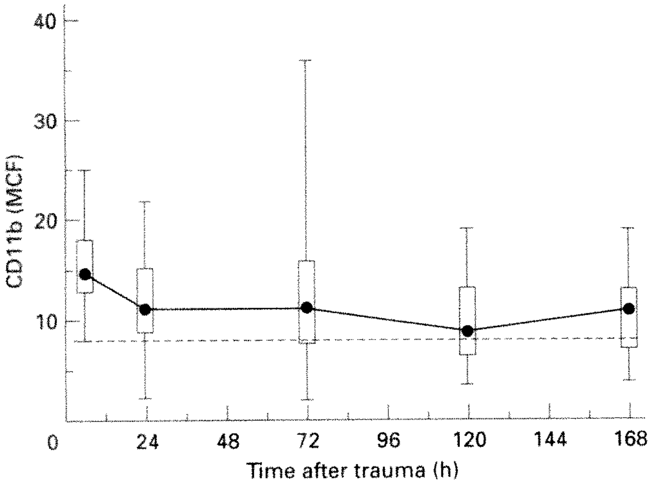

Fig. 3 Polymorphonuclear leucocyte CD11b mean channel fluorescence (MCF) with time following trauma ($n = 31$). Median values (dots), interquartile ranges (boxes), and the maximum and minimum values (bars) are shown. The 95 per cent cut-off for the control group is represented by the dotted line

Effect of sepsis

Eleven of the 31 patients developed sepsis during the course of the study. However, none of the patients studied developed MOFS. There were no significant differences in sE-selectin, sICAM-1 or IL-6 concentrations between patients with and without sepsis at any time. A significant difference in the expression of CD11b was observed in patients with sepsis at 3, 5 and 7 days of the study period (Mann–Whitney *U* test, $P = 0{\cdot}01$) (AUC, $P = 0{\cdot}04$). The E-α_1 PI level appeared to be higher in patients with sepsis than in those without sepsis during the first 3 days of the study period (Mann–Whitney *U* test, $P < 0{\cdot}05$) but this difference was lost over the subsequent 7 days (AUC, $P = 0{\cdot}1$) (*Fig. 4*). There was no difference in ISS between the patients with and without sepsis ($P = 0{\cdot}109$).

The effect of Injury Severity Score

The results were further analysed according to ISS. Two groups of patients were identified. Group A consisted of ten patients with an ISS of 16 or more and group B of 21 patients with an ISS of 15 or less. The release of plasma E–α_1 PI differed significantly between the two groups at all time points with the more severely injured group (A) having significantly higher levels. A similar difference was also seen for serum IL-6 (data not shown). The difference between the two groups in terms of levels of adhesion molecules sICAM-1 and sE-selectin (higher in group A) was significant at day 5 (sICAM-1 and sE-selectin) and day 7 (sICAM-1). However, no significant difference between the two groups was seen in the leucocyte expression of CD11b.

Discussion

It is now believed that an exaggerated systemic inflammatory response may be responsible for the development of MOFS after trauma. However, although many inflammatory mediators have been implicated in this process the overall picture and the key elements remain uncertain. No studies have yet examined a number of elements of each stage of this process from cytokine to neutrophil elastase release in a single group of patients. This study aimed to obtain baseline data on trauma patients who developed a sepsis response although clearly no conclusions can be reached about MOFS from the present data.

The proinflammatory cytokine IL-6 was found to be released rapidly after trauma at levels which were significantly greater in more seriously injured patients. These findings parallel those reported after elective surgery[24] and confirm those of Cruickshank and associates[25] and Hoch *et al.*[26]. Serum concentration of IL-6 therefore represents a sensitive marker of tissue damage and may play an important role initiating the systemic inflammatory response syndrome. The serum IL-6 level was not

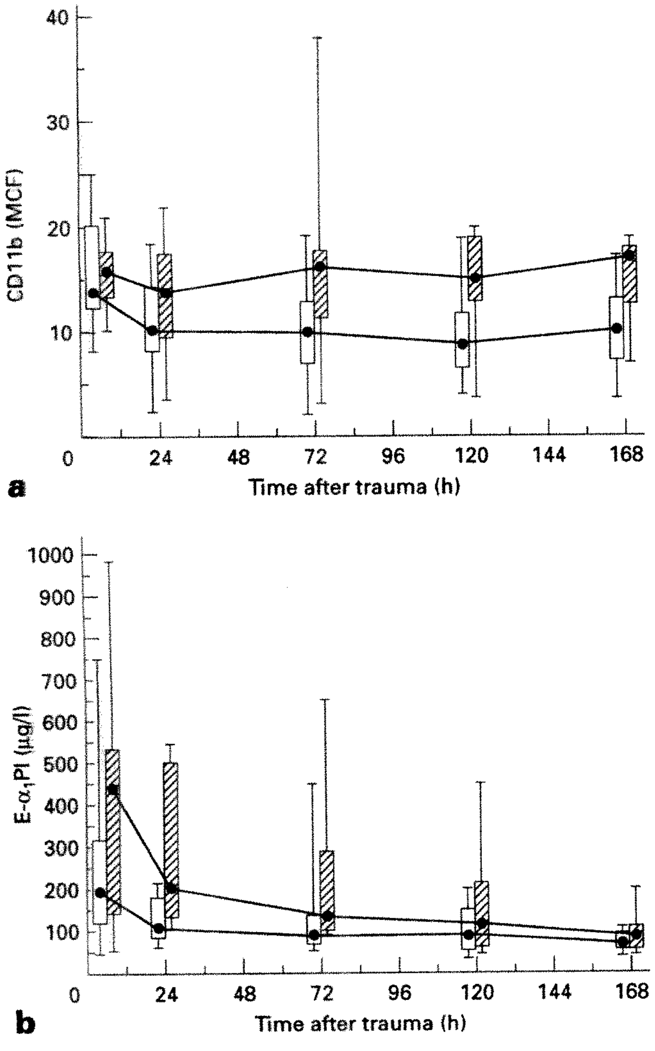

Fig. 4 **a** Polymorphonuclear leucocyte CD11b mean channel fluorescence (MCF) and **b** elastase-α_1 proteinase inhibitor (E–α_1 PI) concentrations with time following trauma in 31 patients subdivided on the basis of development of sepsis ($n = 11$; ▨) or no sepsis ($n = 20$; ☐). Median values (dots), interquartile ranges (boxes), and the maximum and minimum values (bars) are shown. $P = 0{\cdot}04$ (CD11b), $P = 0{\cdot}1$ (E–α_1 PI) (area under the curve) associated with sepsis in this study, although others have found that increased serum levels of IL-6 correlated with a poor outcome in patients with sepsis[27].

In this study the effect of trauma on neutrophil activation was assessed by studying the expression of CD11b surface receptor and measurement of plasma elastase. The levels of the CD11b surface receptor were found to be significantly raised on admission. The degree of upregulation did not correlate with the ISS but was significantly higher in patients who developed septic complications. This finding parallels that of the effects of elective major resectional surgery on neutrophil CD11b expression[22]. Post-traumatic MOFS has also been associated with increased number of CD11b/CD18 receptors on the PMN surface and an upregulation of the oxidative burst[28]. In this study, there was no apparent relationship between neutrophil CD11b expression and sepsis until the third day after injury when the infection was presumably establishing itself in the tissues.

A significantly raised E-α_1PI level was observed on admission which seemed to be higher in those with greater degrees of injury and with the development of sepsis, being significantly raised at day 1 and day 3 compared with that in patients without sepsis. One other study has reported a similar pattern of elastase release but was unable to correlate this with injury severity, probably because of the small group of patients studied[29]. Repetitive increases of plasma elastase have been seen after trauma in patients who developed MOFS[30] although, interestingly, this was also associated with septic complications. Nuytinck *et al.*[31] also reported that raised plasma levels of elastase correlated well with the severity of injury and the occurrence of multiple organ failure. Moreover, these authors were also able to discriminate between later survival or death at an early stage in the clinical course using this parameter. The present data also suggest that significantly raised levels of plasma Eα_1PI may have predictive value on days 1 and 3 for the subsequent development of sepsis syndrome.

Endothelial adhesion molecule expression is also essential for leucocyte adhesion and migration. Both sE-selectin and sICAM-1 levels were found to be raised significantly in the plasma by day 3 following traumatic injury and subsequently increased, the magnitude of the increase being related to the degree of injury. Law *et al.*[32] found a significant correlation between the raised levels of sICAM-1 and the later occurrence of and severity of multiple organ failure but the present study did not show a relationship between sICAM-1 and the occurrence of septic complications.

The data from this investigation confirm that early following trauma, IL-6 is released and neutrophils are activated. Soluble endothelial adhesion molecules were subsequently detectable in the peripheral blood suggesting that receptor–ligand binding between neutrophils and endothelial cells may have occurred. The magnitude of these responses is related to the degree of trauma sustained and some are associated with the subsequent development of sepsis. It is probable that loss of control of this normal inflammatory response syndrome with overstimulation of the parameters involved may be responsible for the widespread tissue damage characteristic of ARDS and MOFS often seen in multiply injured patients. There may be an idiosyncratic genetically determined component of the response to injury which in some individuals results in loss of the normal control mechanisms that attenuate this response, thus allowing it to proceed to widespread tissue injury, clinically manifest as ARDS and MOFS. Indeed, there is now preliminary evidence that the polymorphic expression of another neutrophil receptor, CD16, may be related to the degree of the sepsis response[33].

Activation of the inflammatory processes as suggested by an increase in the level of these markers is the norm even in patients who do not develop ARDS or MOFS, as seen in the present study. Further studies are now required on the input of trauma on the production of negative regulatory cytokines such as IL-10 which has been shown to be upregulated after major surgery[34].

Sentinel node localization in patients with breast cancer

M. M. FLETT, J. J. GOING*, P. D. STANTON and T. G. COOKE

Background Intraoperative lymphatic mapping and identification of the first draining lymph node (the sentinel node) may allow some patients with breast cancer to avoid the morbidity of formal axillary clearance. The aim of this pilot study was to establish the reliability of the technique in predicting axillary node status.

Methods Sixty-eight consecutive patients with breast cancer, 38 undergoing mastectomy and 30 wide local excision, were included. Some 2–4 ml of 2·5 per cent Patent Blue dye was injected into adjacent breast tissue on the axillary side of the primary tumour. After 5–10 min, the axilla was explored. Blue-stained lymphatics were dissected to the sentinel node, which was removed for frozen-section examination, followed by routine histology. Formal axillary dissection was then completed.

Results A sentinel lymph node was identified successfully in 56 (82 per cent) of 68 patients. Histology of the sentinel node accurately predicted axillary node status in 53 (95 per cent). There were three false negatives (5 per cent). In each case, only a single non-sentinel node was tumour positive. Sensitivity and specificity were 83 and 100 per cent respectively.

Conclusion This technique would allow a selective policy of formal axillary dissection in only node-positive patients; however, further experience and refinement are needed.

Axillary node status remains the most important prognostic factor in breast cancer. Formal axillary clearance has remained the best method of breast cancer staging. There is no other reliable method of identifying lymph node-negative patients, using either imaging techniques[1] or pathological characteristics of the primary tumour[2].

Although there is no doubt about the prognostic importance of lymph node status, there is controversy over the extent of axillary surgery required. Axillary dissection is associated with significant morbidity[3,4]. Limited dissection has a lower incidence of morbidity than complete level III axillary clearance. However, axillary node biopsy or sampling has a staging error of 0–42 per cent[5–8] and an increased incidence of axillary recurrence[7,8]. A lower, level II dissection has a staging error of only 2–3 per cent[9,10], and this procedure is preferred by many surgeons.

An alternative strategy of lymph node staging, involving intraoperative lymphatic mapping and identification of the first draining node (the sentinel node), is established in the management of malignant melanoma[11]. Histological evaluation of the sentinel node when compared with the complete lymphatic field shows a high correlation and only a 1 per cent false-negative rate. Preliminary work by Giuliano *et al.*[12,13], using blue dye, suggested that this technique may be applicable to breast cancer. An alternative technique using radiolabelled colloid and a hand-held γ probe has been reported, with similar encouraging results[14,15].

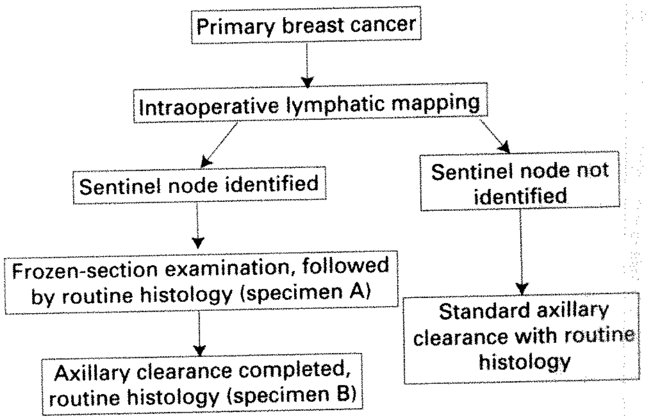
This was a pilot study to verify the reliability of sentinel node localization in predicting axillary nodal status and to carry out a cost analysis in comparison with formal axillary dissection.

Paper accepted 8 December 1997

Patients and methods

The study design is summarized in *Fig. 1*. Sixty-eight consecutive patients with primary invasive breast cancer were included. Mean age was 62 (range 33–86) years. Thirty-eight patients underwent mastectomy and 30 wide local excision, in conjunction with axillary exploration. Informed consent was obtained from all patients.

Intraoperative lymphatic mapping involved injection adjacent to the tumour of 2–4 ml 2·5 per cent Patent Blue dye (Laboratoire Guerbet, Aulney-Sous-Bois, France). After 5–10 min the axilla was explored and the lymphatics were identified and dissected to the sentinel node. An effort was made to ensure that the first draining node had been identified by retrograde dissection of the lymphatic track to the tail of the breast. The sentinel node was removed for immediate frozen-section examination, followed by paraffin-section histology (*Fig. 2*). Formal axillary clearance was then completed. In patients who had a wide local excision, this was carried out through a separate incision. In patients who had a mastectomy, the standard incision



Primary breast cancer
Intraoperative lymphatic mapping
Sentinel node identified
Sentinel node not identified
Frozen-section examination, followed by routine histology (specimen A)
Standard axillary clearance with routine histology
Axillary clearance completed, routine histology (specimen B)

Fig. 1 Design of study to compare intraoperative lymphatic mapping and sentinel node histology with formal axillary dissection in the axillary staging of breast cancer

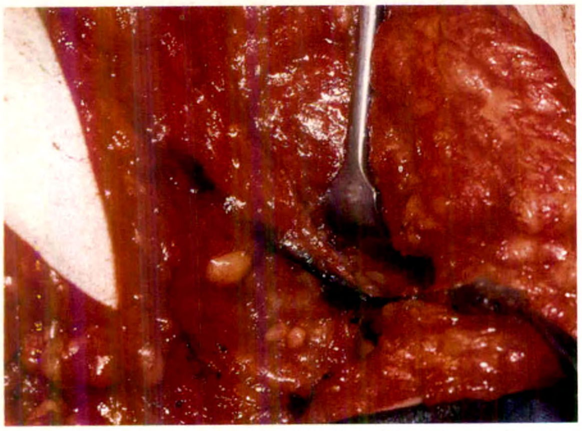


Fig. 2 Intraoperative lymphatic mapping. The blue-stained lymphatic track can be seen leading to the sentinel node, which has been dissected from surrounding fat and is held in dissecting forceps (bottom right). This patient then had a mastectomy

was made and inferior and superior skin flaps were dissected before lymphatic mapping.

All axillary lymph nodes were processed individually for histological examination by a consultant pathologist with a special interest in breast cancer. A full record of operating theatre time was kept to facilitate a cost analysis.

Results

Twenty-one patients (31 per cent) had involved axillary nodes on histology and 47 (69 per cent) were node negative.

Sentinel nodes were identified successfully in 56 patients (82 per cent). In 12, there was more than one sentinel node; a total of 69 was identified.

The histological status of the sentinel node predicted axillary node status accurately in 53 (95 per cent) of 56 patients. There were three false negatives; sensitivity and specificity were 83 and 100 per cent respectively. In five patients the sentinel node was the only positive node recovered from the axilla.

Immediate frozen-section examination of the sentinel node accurately predicted the paraffin-section histology in 53 (95 per cent) of 56 patients. In two patients with positive sentinel nodes, the frozen section was reported as suspicious of metastatic carcinoma. In one, a sentinel node was negative on frozen-section examination, but a single tumour deposit was identified on paraffin section. If formal axillary clearance had been performed on the basis of sentinel node histology, a single patient would have required a second procedure.

Cost analysis

The mean time to dissect and remove the sentinel node was 8 (range 1–18) min compared with 40 (range 20–70) min to complete the axillary dissection. The authors' average theatre costs are £432 per hour. The respective costs of operating time per patient are shown in *Table 1*.

Pathology costs were £95 for frozen section and subsequent histology on the sentinel node, compared with £70 for routine processing of lymph nodes recovered from the axillary dissection specimen.

If sentinel node localization had been used as a staging procedure and a selective policy of formal axillary dissection employed only in node-positive patients, the total operating cost would have been £32 659 compared with £42 106 if routine axillary dissection had been carried out. The respective pathology costs were £7210 and £4760. The combined costs for sentinel node localization were £39 869 compared with £46 866 for routine axillary dissection. The technique of sentinel node localization could have saved £6997 or 15 per cent.

Table 1 Operating time and costs

	Sentinel node localization	Axillary dissection	Total time in operating theatre
Mean (range) theatre time (min)	8 (1–18)	40 (20–70)	86 (60–105)
Cost per patient (at £432 per h)	£57·60	£288·00	£619·20

Discussion

Axillary lymph node dissection is an important staging procedure and has a therapeutic role in reducing the risk of axillary relapse[16]. It is, however, associated with significant morbidity. Seromas requiring aspiration occur in 30–42 per cent of cases[17,18]. Ivens *et al.*[4] found subjective morbidity, interfering with daily living, in 39 per cent of 126 women surveyed 6 months after full axillary clearance.

Reliable prediction of axillary node metastases could help to avoid routine axillary dissection in some patients with invasive breast cancer. However, non-invasive methods have been unsuccessful. Clinical examination[19] and imaging techniques such as ultrasonography, computed tomography and lymphoscintigraphy have largely failed as reliable methods of detecting axillary disease[1].

Limited dissection is an alternative to axillary clearance. In the Edinburgh randomized trial of axillary sampling or clearance[8], a subgroup of 67 patients in whom axillary sampling was performed subsequently went on to have axillary clearance. Twenty-six (39 per cent) had histologically positive nodes and in each case these had been identified on sampling. This contrasts with the results from other studies, showing a staging error rate of 8–42 per cent[5–7]. In one of these studies, involving 473 patients with stage I or II disease, no nodes were identified for histological examination after axillary sampling in 116 patients (25 per cent)[7]. There is conflicting evidence on the value of the qualitative information obtained from axillary sampling. In addition, sampling may not give accurate information on the number of involved nodes, which influences prognosis and often determines the use of adjuvant systemic therapy.

Sentinel node biopsy seems to have sufficient reliability to allow formal axillary clearance to be limited to node-positive patients. Successful lymphatic mapping and localization of the sentinel node is possible in a large proportion of patients and the histology of the sentinel node is highly predictive of axillary node status.

There were three false negatives in this series. However, this rate is low and close to the figure reported for level I and II axillary dissection[9,10]. In each patient only a single non-sentinel lymph node was tumour positive, and in one a micrometastasis was the only evidence of involvement.

This technique is also cost effective. In addition to the saving in operating time and cost, a reduced inpatient hospital stay may be expected if axillary dissection is avoided. Node-negative patients would avoid the potential morbidity of formal axillary clearance. The two previously reported large studies on sentinel node localization in breast cancer have shown similar encouraging results, using two different techniques[13,15]. The techniques may be complementary; lymphatic mapping using a combination of both blue dye and a radiolabelled colloid may be an improvement.

Oesophageal cancer staging using endoscopic ultrasonography

J. VICKERS and D. ALDERSON

University Department of Surgery, Bristol Royal Infirmary, Bristol, UK
Correspondence to: Mr J. Vickers, c/o Department of Surgery, Gloucestershire Royal Hospital, Gloucester GL1 3NN, UK

Background Despite encouraging results from Europe and the USA, endoscopic ultrasonography has yet to become established in the UK for imaging gastrointestinal lesions. The aim of this prospective study was to investigate the accuracy of endoscopic ultrasonography for local tumour (T) and lymph node (N) staging of oesophageal cancer.

Methods Endoscopic ultrasonography was performed in 50 consecutive patients with operable oesophageal cancer. Its accuracy for locoregional tumour staging was assessed and a detailed analysis of the distribution of ultrasonographically detected lymph nodes performed.

Results Endoscopic ultrasonography was highly accurate for both local tumour (92 per cent correct T stage prediction) and lymph node (86 per cent correct N stage prediction) staging compared with final histology. The procedure was also superior to open surgical staging performed by the surgeon; it had a tendency to overestimate malignant involvement of individual lymph nodes and had only limited ability to identify small benign lymph nodes, particularly in the abdomen.

Conclusion Endoscopic ultrasonography was reliable for both local tumour and lymph node staging of oesophageal cancer.

Oesophageal cancer is relatively uncommon in the Western world (UK 5·7 per 100 000; USA 3·2 per 100 000)[1,2]. The rising incidence of adenocarcinoma[2,3], however, and the generally poor prognosis of all oesophageal cancers[4,5] give this disease significant clinical impact. Overall 5-year survival rate is only 5–10 per cent[4,5]. Surgical attempts at cure carry significant morbidity, are costly and are appropriate in only a relatively small number of patients. The rational selection of patients should depend not only on fitness for surgery but also on accurate tumour staging to help identify patients in whom attempted cure is feasible[6].

Endoscopic ultrasonography has been in clinical use in Europe and the USA for over a decade[7,8]. It is valuable for high resolution imaging of gastrointestinal pathology[9,10] and its accuracy in local tumour (T) and lymph node (N) staging in oesophageal cancer is generally reported between 75 and 95 per cent for T stage[11–14] and between 70 and 90 per cent for N stage[15–17], although some series were small[18–20]. There have been no studies of its value for staging oesophageal cancer from the UK. The principal aim of this prospective study was to determine the accuracy of endoscopic ultrasonography for local tumour and lymph node staging in patients with oesophageal cancer compared with surgical and histological staging. A systematic evaluation of the distribution of ultrasonographically detected lymph nodes was also undertaken.

There is increasing evidence that the number and distribution of involved nodes might influence outcome. Metastasis to eight or more nodes[21] and, in particular, the involvement of multiple abdominal nodes[22,23] are both associated with decreased survival. The ability of endoscopic ultrasonography to distinguish between malignant and benign nodes based on morphological characteristics[24–26] makes it useful potentially for individual lymph node assessment.

Patients and methods

Fifty consecutive patients with oesophageal cancer diagnosed by endoscopic biopsy underwent endoscopic ultrasonography evaluation using an Olympus (Olympus Optical, Tokyo, Japan) EUS-M20 radial scanning echo endoscope. None had evidence of haematogenous spread based on a combination of computed tomography (CT) of chest and abdomen, transcutaneous abdominal ultrasonography and plain chest radiograph. All patients were considered fit for surgical resection. Forty-seven patients underwent oesophagectomy within 6 weeks of endoscopic ultrasonography and the remaining three after 8, 9 and 12 weeks. Endoscopic ultrasonography scanning was done on an outpatient basis in a dedicated endoscopy unit. Staging data were gathered from three sources: endoscopic ultrasonography, the surgeon who performed the resection and final histology using a standard examination. Surgical staging data were obtained from direct observation by the principal surgeon according to a standard protocol.

Based on previous experience[16] and trial dissections of individuals scanned at this centre, tumours with contiguous organ invasion (T_4) did not receive surgery. It was considered inappropriate to subject such patients to the extended lymphadenectomy necessary to determine the distribution of nodal involvement.

Endoscopic ultrasonographic T staging was performed by observing directly the depth of penetration of the tumour through the component layers of the oesophageal wall seen on endoscopic ultrasonography as a series of alternating hypoechoic rings[27–30]. T_1 tumours involved the mucosa or submucosa but not the muscularis propria, T_2 tumours involved the muscularis propria but not the adventitia, T_3 tumours were full thickness involving adventitial tissues and T_4 tumours involved adjacent organs by contiguous invasion. Lymph nodes were designated benign or malignant by endoscopic ultrasonography according to the presence or absence of a number of morphological characteristics summarized in *Table 1*. Technical difficulties with the ultrasonography scanner resulted in the exclusion of one patient from lymph node analysis.

Results

Twenty-nine (58 per cent) patients had adenocarcinoma and 21 (42 per cent) had squamous cell carcinoma. Eight

Surgical-T stage	1	17	31	1	79	91	0·97	0·56	0·59

Tumour stage designation as full (T_3 or T_4) or partial (T_1 or T_2) thickness. PPV, positive predictive value; NPV, negative predictive value; EUS, endoscopic ultrasonography. *Calculated against histological stage[31]

tumours were in the middle-third and 42 in the distal-third of the oesophagus. Eleven of the 50 tumours (22 per cent) had caused sufficient luminal stenosis to prevent passage of the echo endoscope beyond the lesion. In these patients endoscopic ultrasonography was incomplete because imaging distal to the tumour was impossible.

Local tumour staging

Table 2 shows close approximation between endoscopic ultrasonography and histology for local tumour staging. Surgical staging was less reliable with a tendency to underestimate the extent of local spread. Comparison of endoscopic ultrasonography with histological staging for individual patients revealed four staging errors (8 per cent). Three were a result of overstaging, all T_2 tumours incorrectly designated T_3 by endoscopic ultrasonography. A single T_3 lesion was understaged as T_2 by endoscopic ultrasonography. Nine (18 per cent) surgical staging errors were made compared with final histology. Eight were understaging errors, all T_3 tumours incorrectly designated T_2 by surgical staging, and one was overstaging of a T_2 tumour as surgical-T_3.

Overall sensitivity and specificity values have been calculated for T stage by distinguishing between full- and partial-thickness tumours (*Table 2*). Some 97 per cent of full-thickness tumours (T_3 or T_4) were detected accurately by endoscopic ultrasonography with high sensitivity and positive predictive value. Surgical staging was inferior to endoscopic ultrasonography in the detection of full-thickness tumours.

Lymph node stage

Forty-one patients were designated N_1 by endoscopic ultrasonography and eight were N_0. The median number of nodes detected per patient (not categorized as either malignant or benign) was four (interquartile range 3–6).

Seven (14 per cent) lymph node staging errors were made by endoscopic ultrasonography; six were overstaging errors. Ten (20 per cent) staging errors occurred with surgical staging, of which seven were understaging and three were overstaging errors (*Table 3*). Sensitivity and specificity values for both endoscopic ultrasonography and surgical lymph node staging compared with histological staging are also shown in *Table 3*.

Endoscopic lymph node detection

Table 4 compares the predicted malignant involvement of lymph nodes detected by endoscopic ultrasonography with all malignant nodes detected by histology. The malignant : benign ratio of the nodes detected by endoscopic ultrasonography was almost 1 : 1, although more lymph nodes in total were detected by histology than endoscopic ultrasonography at a ratio of almost 2 : 1. The total numbers of malignant nodes detected by each modality were virtually identical, most of the additional nodes detected histologically were benign.

There was good agreement between the total number of mediastinal nodes detected by endoscopic ultrasonography and histology, but far fewer abdominal nodes were detected by ultrasonography than by histology (*Table 5*). Even after exclusion of the 11 patients with obstructing oesophageal lesions (in whom ultrasonic evaluation of abdominal nodes was not possible) there was still a large difference between the number of abdominal nodes detected by ultrasonography and histology. The former detected five times as many mediastinal nodes as abdominal nodes, whereas with histological examination the ratio was nearer 1:1 (*Table 5*). The majority of nodes missed by endoscopic ultrasonography were benign and lying below the diaphragm. Almost equal numbers of malignant nodes were detected by ultrasonography and histology (*Table 3*).

Lymph nodes detected above and below the diaphragm were divided into malignant and benign groups and the data compared. In the mediastinum endoscopic ultrasonography identified virtually the same total number of lymph nodes as final histology (197 *versus* 204), but ultrasonography overestimated the malignant status of individual nodes (93 of 197 for endoscopic ultrasonography *versus* 64 of 204 for histology). A different situation existed with abdominal nodes (*Table 5*). Endoscopic ultrasonography detected very few abdominal lymph nodes in total compared with histology (39 *versus* 173 for the 38 patients with a patent oesophagus). Furthermore, far fewer nodes were identified as malignant by ultrasonography (20 of 39) compared with histology (36 of 173).

The detection rates of neoplastic nodes by endoscopic ultrasonography and histology for each patient were evaluated to determine agreement, excluding the 11 patients in whom malignant oesophageal obstruction prevented examination of abdominal nodes by endoscopic ultrasonography.

Endoscopic ultrasonography tended to overestimate lymph node involvement (*Fig. 1*), although where overestimation occurred, it was usually by a single lymph node at most. Significant discrepancies in lymph node counts (over four) between endoscopic ultrasonography and histology occurred in only three patients. Assessing these patients individually, in one, overestimation of the malignant involvement of detected nodes was the source of error, whereas in the other two, the discrepancy was due to failure of endoscopic ultrasonography to detect large numbers of involved abdominal lymph nodes. In the remaining 35 patients, however, agreement was much closer between the two techniques. Exact agreement between the malignant lymph node counts occurred in only 16, although a match within a single lymph node was achieved in 30 patients.

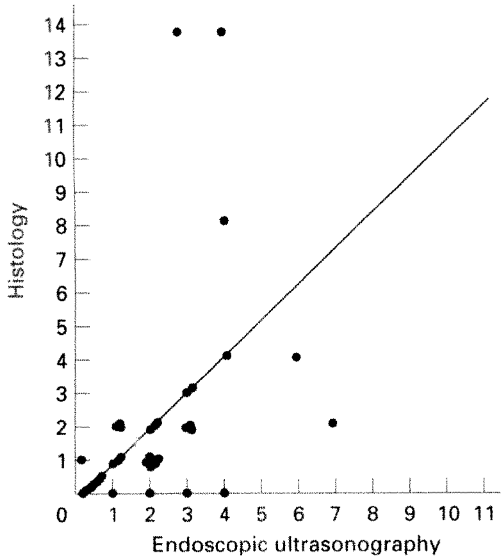

Fig. 1 Agreement for malignant node detection: endoscopic ultrasonography *versus* histology (malignant nodes per patient)

Discussion

This study has shown that endoscopic ultrasonography is highly accurate for the prediction of local tumour infiltration when compared with histology[17,32,33], and superior to open surgical assessment. It is not as reliable for lymph node staging, particularly in node-negative patients, but is still superior to surgical assessment of lymph node stage.

The reliability of endoscopic ultrasonography for local tumour staging has important clinical implications[34]. It aids the preoperative identification of patients with a tumour that has not yet penetrated the full thickness of the oesophageal wall. For resectable tumours the distinction between partial- and full-thickness penetration is an important determinant of long-term survival[35] and local recurrence[36]. Endoscopic ultrasonography can therefore identify patients in whom a surgical cure may be possible, if they are also lymph node negative. Patients with full-thickness tumours are less likely to be cured by surgery alone but, with the continuing development of chemoradiotherapy techniques, endoscopic ultrasonography may help identify patients who could benefit from neoadjuvant therapy. The preoperative identification of individuals with contiguous organ invasion, which renders tumours irresectable, rationalizes the use of resources and prevents unnecessary surgery[16,37]. There is a valid argument for the selection of therapeutic regimens other than radical surgery with its attendant morbidity and mortality[5,38], in patients with little or no prospect of cure.

Accurate lymph node evaluation is important because node stage also affects prognosis[35]. Only 50 per cent of patients with lymph node metastases will be alive 2 years after resection, and just 15 per cent survive more than 5 years[39]. The actual number of involved lymph nodes might also be important. Recent evidence suggests that the presence of a large (more than seven) number of involved nodes, and in particular multiple abdominal nodes, is associated with reduced survival[21,22,40]. Consequently, a subgroup of patients might once again be identifiable who might benefit from non-surgical therapy. Oesophagectomy alone is appropriate treatment for patients with partial-thickness, lymph node-negative tumours.

This study has identified two important sources of error for lymph node evaluation by endoscopic ultrasonography. First, some benign lymph nodes detected in the mediastinum were incorrectly designated malignant. The identification of nodes by endoscopic ultrasonography does not necessarily imply nodal metastasis. Possible sources of error include classification of large nodes as malignant rather than reactive, and errors in the interpretation of ultrasonic lymph node characteristics. The development of ultrasonographically guided fine-needle aspiration cytology could enhance staging accuracy.

The second limitation of endoscopic ultrasonography is its failure to detect many of the regional nodes in the abdominal cavity. The majority of nodes that were 'missed' by endoscopic ultrasonography were small and benign[41], although many malignant abdominal nodes were also missed. Small, malignant abdominal nodes, however, rarely occurred in isolation, so this had little impact on overall staging accuracy.

The overall impact of these sources of error is quite small. Lymph node staging was correct in 85 per cent of all patients, and the individual identification of malignant nodes matched final histology to within a single node in 80 per cent of cases.

In this study, overall T and N staging accuracy was not greatly affected by obstructing oesophageal tumours. Obstructing tumours were almost always T_3 N_1, detectable on limited mediastinal scanning alone. Important prognostic information about coeliac node involvement is, however, not available if abdominal endoscopic ultrasonography cannot be performed. Endoscopic ultrasonography from within the stomach is technically more demanding than from within the oesophagus. Not all lymph nodes present are within scanning range. The failure of endoscopic ultrasonography to detect every single lymph node present might, however, be of little clinical importance, provided that it detects malignant nodes reliably and only fails to detect mainly benign nodes.

In future, node staging is worthy of further study with endoscopic ultrasonography although a number of technical advances will be needed to improve its accuracy. The availability of scanners using higher frequency ultrasonography than 12 MHz will increase image resolution. As experience increases in the more technically difficult technique of gastric endoscopic ultrasonography, the ability to detect lesser curve and coeliac nodes may improve. The additional preoperative staging data provided by endoscopic ultrasonography and its impact on patient selection and long-term outcome will require careful assessment.

Influence of luminal obstruction on oesophageal cancer staging using endoscopic ultrasonography

J. VICKERS and D. ALDERSON

University Department of Surgery, Bristol Royal Infirmary, Bristol, UK

Background Endoscopic ultrasonography is technically limited in patients with obstructing oesophageal cancers if the endoscope cannot pass beyond the lesion. This problem may be overcome by preliminary endoscopic tumour dilatation, or by the use of narrower calibre 'blind' endoscopic ultrasonographic telescopes or fine-bore endoscopic ultrasonographic miniprobes. These alternatives are either potentially hazardous or time consuming and expensive. The aim of this prospective study was to determine the effect of oesophageal obstruction on the locoregional staging accuracy of endoscopic ultrasonography for oesophageal cancer.

Methods Some 50 patients with oesophageal cancer underwent staging with endoscopic ultrasonography before oesophagectomy and the T and N stage determined by endoscopic ultrasonography was compared with final histology. In 11 cases of luminal obstruction no attempt was made to overcome the blockage and a limited mediastinal scan alone was performed.

Results Malignant obstruction of the oesophagus did not greatly reduce the staging accuracy of endoscopic ultrasonography. It correctly assessed local infiltration in all patients with obstruction, and correctly predicted nodal stage in nine of 11 patients.

Conclusion Tumours large enough to cause luminal obstruction are nearly all full thickness (T_3), and frequently have mediastinal lymph node metastases (N_1) at the time of examination. This can usually be detected from limited endoscopic ultrasonography within the mediastinum.

Endoscopic ultrasonography is an imaging technique which combines high-frequency ultrasound and conventional endoscopy in a single instrument. It provides high-resolution images of the gastrointestinal tract wall and adjacent structures[1,2]. There is mounting evidence to show that, in patients with oesophageal cancer, endoscopic ultrasonography is the most accurate preoperative local tumour and lymph node staging investigation[3–5]. It is the only imaging modality that can demonstrate the precise depth of mural invasion[6] and can detect regional and more distant lymph nodes down to just a few millimetres in diameter[7]. It also demonstrates their internal structure, allowing prediction of individual lymph node status, based on sonographic characteristics, rather than size alone[8,9].

One commonly reported limitation of endoscopic ultrasonography is that a significant proportion of tumours obstruct the oesophageal lumen[10,11], preventing assessment of distal parts of the primary tumour, distal mediastinal structures, the stomach and the abdominal lymph nodes. One possible solution to this problem is endoscopic tumour dilatation before endoscopic ultrasonography thereby permitting a full staging examination[12]. The use of fine-bore ultrasound miniprobes has been advocated as a means of overcoming malignant obstruction[13], but the equipment is expensive and the instruments cannot be steered. More recently, relatively narrow, steerable, but optically blind ultrasonography endoscopes have been developed to help traverse some stenotic lesions. Time consuming or potentially dangerous procedures such as these may not be justified if the staging accuracy of endoscopic ultrasonography is not significantly reduced in such cases of tumour obstruction.

The aim of this study was to compare the staging accuracy of endoscopic ultrasonography with final histological stage using the tumour node metastasis (TNM)[14] staging system for obstructing and non-obstructing oesophageal cancers in patients with operable tumours undergoing oesophagectomy.

Patients and methods

Fifty consecutive patients with potentially resectable oesophageal cancer underwent preoperative tumour staging with endoscopic ultrasonography using a 13-mm diameter Olympus EU-M20 radial scanning echo endoscope (Olympus, Tokyo, Japan). All patients were considered fit for surgery, with no evidence of haematogenous metastasis on computed tomography. Predictions of the local tumour stage (T) and regional lymph node stage (N) using the TNM system were made using endoscopic ultrasonography and compared with the final histological stage, following oesophagectomy. The endoscopic ultrasonography stage was not used to influence the decision to perform resection, which was carried out in all 50 patients. The proportion of patients in whom only a limited (proximal) endoscopic ultrasonographic investigation could be performed because of malignant obstruction of the oesophagus was determined and the staging accuracy of endoscopic ultrasonography for patients with obstructing and non-obstructing lesions was compared with the final histological stage. When assessing lymph node involvement, data from a single patient were excluded because of a technical fault with the echo endoscope during scanning.

Results

Passage of the echo endoscope was prevented by malignant obstruction in 11 (22 per cent) of 50 patients. In these cases examination was restricted to the upper part of the primary tumour and mediastinal structures

---

Paper accepted 2 February 1998

proximal to the obstruction. In the other 39 patients a full staging investigation was performed, including distal assessment of the stomach, and coeliac axis, lesser and greater curve lymph nodes.

Endoscopic ultrasonography predicted full-thickness wall penetration, but without contiguous organ invasion (T_3) in 41 of the 50 tumours and malignant lymph node involvement in 41 of 49 patients. For comparison, on final histological examination 39 tumours were found to be full thickness (T_3 lesions) and 36 were lymph node positive (N_1).

Of the 11 tumours that obstructed the oesophageal lumen all were T_3 histologically. Despite the limited endoscopic ultrasonographic examination performed in these patients, endoscopic ultrasonography correctly identified all tumours as full-thickness lesions (T_3) (*Table 1*).

Endoscopic ultrasonography designated all 11 tumours as N_1 lesions, even though nodes could only be visualized in the mediastinum proximal to the tumours (median 3 (range 1–5) malignant nodes per patient). Histological N staging compared favourably with endoscopic ultrasonography results; nine of the 11 patients were lymph node positive on histological examination (*Table 1*) (median 2 (range 0–5) malignant nodes per patient). Accurate T and N staging information was therefore readily obtainable by endoscopic ultrasonography in every patient for local tumour stage and in nine of 11 patients for regional node stage, without scanning distal to the tumour.

Abdominal lymph nodes cannot be detected if the echo endoscope does not pass distal to the primary tumour and this may be clinically important. A total of 18 malignant abdominal nodes were detected by histological examination of the resected tumour specimens in six of the 11 patients with obstruction (range 1–5 malignant nodes per patient). On final histology five were designated lesser curve nodes, eight left gastric nodes, two greater curve nodes and three were unspecified. The maximum recorded size was 1·8 cm and the minimum 0·5 cm. In all six of these patients, however, histologically malignant mediastinal nodes were also present (N_1) and in each patient this feature was detected successfully by a limited (i.e. proximal mediastinal) endoscopic ultrasonographic scan alone.

For the 50 patients there were only four T staging errors made by endoscopic ultrasonography (sensitivity 97 per cent, specificity 73 per cent, positive predictive value (PPV) 0·93, negative predictive value (NPV) 0·89). Overstaging occurred three times and understaging once (*Table 2*). A further seven lymph node staging errors were made by endoscopic ultrasonography (sensitivity 97 per cent, specificity 54 per cent, PPV 0·85, NPV 0·88). Lymph node status was overstaged by endoscopic ultrasonography six times and understaged once (*Table 2*). All four local tumour staging errors occurred in patients whose oesophageal lumen was patent and in whom a complete staging examination had therefore been performed. Only two of seven lymph node staging errors occurred in patients with malignant obstruction.

Discussion

Malignant oesophageal obstruction leading to incomplete endoscopic ultrasonographic examination occurred in 22 per cent of patients ($n = 11$), a similar rate to that seen in other series[10,11,15]. Ten impassable lesions were encountered in the first 25 patients and only one in the next 25 suggesting that moderately tight stenoses can be overcome with experience.

Local tumour penetration was assessed correctly for all obstructing tumours as endoscopic ultrasonographic T_3 lesions, confirmed by final histology. Lymph node involvement was correctly assessed in nine of the 11 obstructing tumours. The presence of malignant oesophageal obstruction therefore made little difference to the T and N staging accuracy of endoscopic ultrasonography for oesophageal tumours. In the complete series of 50 patients, most of the staging errors made by endoscopic ultrasonography occurred in patients in whom there was no oesophageal obstruction and in whom a full staging examination had therefore been carried out.

There was a clear relationship between luminal obstruction and the local tumour and lymph node stage. Oesophageal tumours that were advanced enough to obstruct the passage of a 13-mm diameter echo endoscope tended to be locally advanced (T_3)[15] with regional lymph node metastases already present at the time of examination[16,17]. Even limited endoscopic ultrasonography at the level of or proximal to the obstructing tumour revealed both of these key features in most patients.

In this study the T and N stage was usually assessed correctly by endoscopic ultrasonography in patients with obstructing lesions. It is true, however, that not every aspect of the tumour anatomy will necessarily be revealed by such limited scanning. Potentially important prognostic information about coeliac node involvement, in particular, is not available. This is significant because spread to coeliac and cervical lymph nodes is currently classified as distant (M_1) rather than regional (N_1) spread.

Failure to pass every tumour may be more important in upper and middle third tumours where local airway infiltration or fixation to great vessels is more likely, and where understaging a T_4 tumour could lead to unnecessary surgery for unresectable disease. It is conceivable that only the distal portion of an obstructing tumour, beyond the reach of endoscopic ultrasonography, may be T_4 while the proximal portion is staged as T_3. This situation is less problematic with distal third tumours, as aortic, pericardial and pulmonary involvement are not common and can still usually be dealt with by excision. Although all the patients in this study had potentially resectable tumours, other studies have shown endoscopic ultrasonography to be generally reliable for detecting contiguous invasion (T_4 lesions)[18,19].

For the purposes of locoregional tumour staging alone, it is therefore difficult to justify the use of potentially hazardous procedures, such as endoscopic tumour dilatation to facilitate more distal passage of the echo endoscope, merely to complete the scan. Tumour dilatation may be necessary for nutritional purposes, in which case a complete scan may then be performed, although the only likely advantage would be the identification of further gastric and coeliac lymph node metastases, in patients who also have mediastinal spread. It is similarly difficult to justify the expense of fine-bore, non-steerable, high-frequency miniprobes[5,13] to negotiate tight strictures, when this may add little to overall staging accuracy. The development of narrower diameter, but steerable echo endoscopes ('oesophagoprobes') may be a useful compromise between bulky, conventional echo endoscopes and non-steerable miniprobes, and should render fewer tumours truly impassable.

Background Antireflux surgery is a highly effective treatment option in patients with severe gastro-oesophageal reflux disease. However, because of the increasing pressure of cost containment within health care, cost aspects must also be added to the decision-making process.

Methods The aim of this analysis was to assess the total cost of open antireflux surgery during the first year after operation in 178 patients with chronic reflux, who were recruited into a controlled, prospective clinical trial. The study was carried out in 17 hospitals in the Nordic countries.

Results The cost of the operation represented more than 90 per cent of the direct medical costs which amounted to approximately US $5700. For a patient in the work force the indirect cost, i.e. loss of production, represented 47 per cent of the total cost, which was about US $10 800.

Conclusion The total cost profile of open antireflux surgery has now been established prospectively and can form a basis for future comparisons.

Antireflux surgery is highly effective in permanently controlling symptoms with few failures, the majority of which seem to occur during the early postoperative period[1–4]. However, modern medical therapy is also effective in the long term[5,6]. Therefore, in the choice between different therapeutic strategies in chronic gastro-oesophageal reflux disease (GORD), different aspects, which are fundamentally different in character, have to be added to the decision-making process. One important factor is the cost. Unfortunately, very few controlled prospective clinical data are available to allow proper definition and characterization of the true costs of different therapies for chronic diseases in general and GORD in particular. The aim of this analysis was therefore to present the total costs for open antireflux surgery during the first year after operation when a variety of hospitals in the Nordic countries were engaged in the protocol. The main reason for focusing on this limited 1-year period was that the bulk of the cost associated with the surgical therapeutic option occurs during this period.

Patients and methods

Eligible for inclusion in the study were patients with chronic reflux symptoms and documented oesophagitis at endoscopy. These patients were initially given omeprazole either 20 or 40 mg daily for up to 4 months to control symptoms and to heal the oesophagitis. One hundred and fifty-four patients were initially randomized to have antireflux surgery within 3 months of the randomization, but ten of these patients subsequently refused operation. Among the patients recruited originally, 34 had an incomplete symptom response and/or endoscopic healing when taking omeprazole 40 mg daily, whereupon they were offered antireflux surgery according to the protocol and ultimately accepted an operation. Therefore, in total 178 patients, with a mean age of 50 (18–74) years, were operated on, of whom 75·3 per cent were men (*Table 1*). There were no important differences in the demographic profile of those initially randomized to surgery and those having an incomplete symptomatic response to omeprazole (*Table 1*). The majority of patients had a history of reflux disease lasting more than 5 years. At preoperative endoscopy 115 patients had grade 2 oesophagitis, 41 grade 3 disease and 21 grade 4 disease as assessed according to a predefined protocol[7].

The participating centres and the investigators responsible have been presented elsewhere[8]. All operations were carried out under general anaesthesia through an upper midline incision; 121 patients had a 360° total fundic wrap and 53 had a semi-fundoplication according to Toupet or slight modification of this partial fundoplication[9–11]. Five patients had a posterior gastroplexy according to Hill combined with a highly selective vagotomy[12].

The mean operating time was 103 (range 40–240) min. The mean hospital stay was 7·3 days. The postoperative course and complication rates have been described in detail elsewhere[8]; five patients (2·8 per cent) required splenectomy. During the

immediate postoperative period, six patients experienced complications which required operative reintervention. Forty-six patients had one postoperative adverse event, only three had three or more complications. During the first postoperative year, 14 patients (seven operated) were diagnosed to have an incisional hernia and one patient had a reoperation for recurrent reflux. During the year after operation, moderate to severe reflux symptoms were reported by 19 patients (10·7 per cent) at least once during the first 3 months. Persistent reflux symptoms, requiring omeprazole therapy, were noted in ten patients (5·6 per cent).

Assessment and calculation of costs

A prospective protocol was used to register all costs which appeared during the management of the patients during the first year of the study.When there was no observation under a specific item, no cost was registered. Both direct and indirect costs were considered. The direct medical costs included antireflux surgery, days in hospital, visits to a doctor, visits to a nurse, endoscopy, medical therapy in case of relapse, reoperation or other surgical procedures. Additional direct costs were those associated with travelling. Indirect costs were assessed in the form of loss of production due to absence from work in association with the operation and hospital visits.

The unit cost of an operation, reoperation, hernia surgery and endoscopy are from internal, prospective assessments done at Sahlgrenska University Hospital, Gothenburg, Sweden. The cost of an operation included the so-called hotel cost (days in hospital). The cost of an outpatient visit to a doctor was set equal to the mean cost of an outpatient visit to a Swedish county hospital (Landstingsförbundet, 1995). The cost of a visit to a nurse was set at 25 per cent of that to a doctor. The cost per 20 mg capsule of omeprazole was derived from the retail price of a package of 28 capsules.

The cost per minute of travel by private car was arrived at by creating a relationship between time and distance, based on 559 eligible questionnaires, and an assumed cost of 25 Swedish crowns (SEK) per 10 km. With regard to public transport and taxi the questionnaire included a question on the cost. Hence, it was possible to establish a direct relationship between time and cost. Based on 144 questionnaires filled in by Swedish patients, the cost of travelling by public transport and taxi was 0·41 and 7·60 SEK per min respectively. Other modes of transport were assumed to result in no cost.

The cost per hour of absence from work equalled the cost per hour for an industrial worker in Sweden during the actual time period. In May 1995 this total cost was 153·50 SEK (US $19·4).

Hospital visits and endoscopies not likely to occur in clinical practice were excluded from the main analysis (protocol-driven visits and endoscopies occurring despite the fact that the patient was asymptomatic). However, for comparison, costs were also calculated with all visits and endoscopies included.

It was assumed that trial-wide non-monetary quantities could be applied to each of the four participating Nordic countries, except the extent of sick leave, which was assumed to be country-specific. Monetary costs were calculated for Sweden, i.e. the non-monetary quantities were multiplied by appropriate Swedish unit costs and are expressed in US$ (in January 1998 1 US$ = 7·9 SEK).

The protocol and the case record forms were approved by the local ethics committees. Before entry into the trial all participants gave their written informed consent.

Results

Non-monetary quantities

The resource consumption in non-monetary terms is presented in *Table 2*. The mean hospital stay was 7·3 days. The 'as clinical practice' approach included 178 follow-up visits after surgery, nine extra visits and 16 protocol-driven visits necessitated by moderate or severe reflux symptoms and/or specific postoperative complaints. With the 'all visits included' approach, another 221 protocol-driven visits were included. The two approaches resulted in 1·1 and 2·9 visits to a doctor per patient respectively. In addition, there were 0·6 visits (109 in total) to a nurse. The number of endoscopies were accordingly calculated in two ways. The two approaches resulted in 0·2 and 1·0 endoscopies per patient respectively.

Table 2 Direct medical costs and indirect costs per patient submitted to antireflux surgery

Cost item	Quantity (mean no. per patient)	Cost per unit (US$)	Cost per patient (US$)
Direct medical costs			
Operation	1	5307	5307
Days in hospital	7·3	—*	
Outpatient visit (doctor)	1·1 (2·9)	165	181 (478)
Outpatient visit (nurse)	0·6	41	26
Endoscopy	0·2 (1·0)	141	28 (141)
Omeprazole	4·2	2·7	11
Reoperation	0·01	6267	63
Other surgical procedures	0·04	2555	102
Total direct medical cost			5718 (6126)
Indirect medical costs			
Absence from work			
Outpatient visit	0·6 (2·2) h	19·4	12 (43)
Endoscopy	0·5 (2·7) h	19·4	10 (52)
GORD symptoms and operation (per patient)	16·5 days	155	2557
Total indirect cost			2579 (2674)

Values in parentheses are corresponding figures, when all visits and endoscopies are included. *Included in cost of surgery. GORD, gastro-oesophageal reflux disease

As already noted, reflux relapse requiring omeprazole therapy was noted in ten patients. In addition, three patients received omeprazole therapy without having persistent reflux symptoms. Altogether these 13 patients consumed 746 20 mg capsules of omeprazole, a mean of 4·2 capsules per patient.

Reoperation was performed in one patient and repair of an incisional hernia in seven patients.

Based on 559 eligible questionnaires answered at outpatient visits the total travelling time per visit was estimated at 68 min. Private car and public transportation were the two most common modes of transportation.

In 260 of 628 eligible questionnaires the patient reported that he/she would have been working if not visiting the clinic. In 92 questionnaires the patient reported the assistance of a companion, 20 of whom reported absence from work due to the visit.

Data on sick leave in connection with operation were collected from the regional insurance office for patients at three centres in Sweden. Of 41 patients operated on at these centres sick leave was reported by 27 patients. On average, these patients had 47·2 days on sick leave. Assuming that approximately 70 per cent are days of absence from work, the number of days absence from work due to surgery was 33·0 per patient in the work force. Since the rate of employment among the patients in the study was 50 per cent, the average number of days absent from work was estimated to be 16·5 per patient.

Table 3 Cost per patient associated with antireflux surgery

	Cost (US$)		
	For a patient not in work	For a patient in work	Per patient (50% in work)
Direct medical cost	5718 (6126)	5718 (6126)	5718 (6126)
Transport cost	42 (78)	42 (78)	42 (78)
Indirect cost		5091 (5164)	2579 (2674)
Total cost	5760 (6204)	10 851 (11 368)	8339 (8878)

Values in parentheses are corresponding figures when all visits and endoscopies are included

Costs

The accumulated cost during the first year after and including antireflux surgery is given in *Table 2*. The travelling time reported in the questionnaires was multiplied by the mean number of trips necessitated by operation. Mean travel cost per patient was 42 US$. There were 0·7 visits to a doctor or nurse per patient (2·5 with 'all visits included' approach) and in 41·4 per cent of the visits the patient recorded absence from work due to the visit. In addition at 3·2 per cent of the visits the patient reported that he/she had a companion who was absent from work. Hence, the mean number of hours absence from work due to outpatient visits was 2 × 0·7 × 0·446 = 0·6 h (2 × 2·5 × 0·446 = 2·2 h for all visits including protocol-driven visits). Furthermore, 0·2 endoscopies were done per patient (1·0 with 'all visits included' approach) and it was assumed that each endoscopy resulted in a 6-h absence from work.

Given that half of the patients with GORD were working, the total average cost for antireflux surgery amounted to 8339 US$, when based on clinical practice and to 8878 US$, when all study visits and endoscopies were included. When based on clinical practice, the direct medical cost constituted close to 70 per cent of the total cost, and the costs of operation represented more than 90 per cent of the direct medical cost (*Tables 2 and 3*). However, for a patient in the work force the total cost increased to 10 851 US$. For these patients the direct medical cost dropped to some 53 per cent of the total cost.

Discussion

The two most significant observations in this prospective assessment of the first year's cost of open antireflux surgery were that the cost of an operation represented more than 90 per cent of all direct medical costs, and that for a patient in the work force the indirect cost, i.e. loss of production, represented 47 per cent of the total cost.

The profound impact of the cost of the operative procedure has several important implications. First, it stresses the importance of accurate cost estimates. This is a significant problem in many health economic assessments. Charges and diagnosis-related group estimates are often used as approximations for the true cost. In this study the cumulative costs of antireflux surgery, assessed prospectively and in very detailed manner at one large hospital, were used to define the mean cost of the operations. Second, the cost of operation, and therefore the total cost, may vary substantially between different hospitals depending upon, among other things, local routines, organization and also the experience of the surgical team. Third, the limited weight of direct medical costs other than the cost of operation means that it may be possible to fairly correctly model the first year's direct medical cost given an accurate estimate of the cost of operation. However, this information can not of course be directly transferable to a model comparing surgery and medical treatment. Based on such a model it was concluded that operation appeared to be a cost-effective treatment option in patients with severe or refractory GORD compared with medical treatment[13,14] if the latter therapy lasted longer than approximately 4 years[15]. On the other hand, in another model it was found that surgery and medical treatment were equally cost-effective only if the follow-up time was extended to 9 years[16]. It is evident that prospective, controlled clinical trials, including assessments of costs, must be carried out to allow more comprehensive conclusions to be drawn. Finally, significant reductions in direct medical costs in the first year following operation can only be achieved by reducing the costs of operation including the hospital stay. The most promising surgical development is laparoscopic fundoplication[4,17], although the operating time is somewhat longer with this technique, the hospital stay is substantially reduced.

The number of days on sick leave in connection with surgery also deserves comment. First, the inclusion of indirect costs in a health economic analysis is controversial, since the range of costs included will depend very much on the true perspective of the analysis. The narrower the perspective, the narrower will be the relevant range of costs. However, all costs should in principle be considered, including the loss of production due to the disease or its treatment. On the other hand, there is disagreement about how absence from work should be validated[18,19]. In this analysis the common approach of attaching the total labour cost per hour to each hour of absence was used. It has been argued, however, that this approach may result in an overestimation of the true cost, especially when there is unemployment or when non-urgent work may be postponed[20]. A more general concern regarding the inclusion of indirect costs is that it favours intervention in diseases where most sufferers are among those in the work force. While this concern is valid and should be kept in mind when different diseases are compared[21], the authors believe it should not lead to the exclusion of indirect costs in individual analyses. Furthermore, the many days of sick leave observed in this study and the substantial impact of indirect costs on the total cost for a patient in the work force imply that modelling of the total cost, i.e. when assumptions are utilized to a large extent, may be very hazardous. Finally, the importance of sick leave points for the total cost profile highlights another area with potential for cost reduction. With laparoscopic fundoplication, sick leave is significantly reduced[4].

On the other hand, the present analysis has not considered so-called intangible costs, i.e. costs associated with pain, suffering and changes in social functioning[18,19]. These costs are generally very difficult to define in monetary terms. This issue is even more complicated in any analysis including surgical treatment, which is expected to result in future intangible benefits for the patient in the form of avoidance of relapses and other clinical consequences of uncontrolled GORD. Another methodological consideration in the assessment of intangible benefits between different treatment options is that these can at least partly be addressed by studying quality of life indices[22].

In conclusion, the present prospective, controlled multicentre trial has established a total cost profile of open antireflux surgery. The cost is profoundly influenced by the cost of the operative procedure with direct medical costs amounting to about 5700 US$. For half of the patients, who were in the work force, additional indirect costs of about 5000 US$ must be added resulting in a total cost of about 10 800 US$.

Efficacy of anterior, posterior and total fundoplication in an experimental model

D. I. WATSON, G. MATHEW, G. K. PIKE, R. J. BAIGRIE and G. G. JAMIESON

University Department of Surgery, Level 6, Royal Adelaide Hospital, Adelaide, South Australia 5000, Australia
Correspondence to: Mr D. I. Watson

Background This study examined the effect of different types of laparoscopic fundoplication on an incompetent lower oesophageal sphincter to test their effectiveness at preventing gastro-oesophageal reflux in the early postoperative period.

Methods An experimental porcine model was used. Initial oesophageal myotomy ensured an incompetent lower oesophageal sphincter with free reflux of 'intragastric fluid'. Anterior, posterior or total fundoplication was then performed laparoscopically in 15 laboratory pigs (five in each group). Fundoplication competence and efficacy were determined 2 weeks after laparoscopic antireflux surgery by inflating the stomach with liquid through a gastrostomy cannula. Some animals were also studied at 4 and 6 weeks. Lower oesophageal sphincter pressure was determined using a water-perfused oesophageal manometry catheter incorporating a Dent sleeve.

Results All three types of fundoplication produced similar increases in postoperative resting lower oesophageal sphincter pressure and restored adequate competence to the gastro-oesophageal junction.

Conclusion All three variants of laparoscopic fundoplication restore gastro-oesophageal competence in the early postoperative period.

The technique of Nissen's original total fundoplication has been modified progressively in order to reduce the likelihood of adverse outcomes following fundoplication for gastro-oesophageal reflux[1]. One variation has been the construction of a partial rather than a total fundoplication, with the fundus sutured either behind[2] or in front[3] of the intra-abdominal oesophagus. Which type of fundoplication is most effective and associated with the lowest incidence of adverse sequelae, however, continues to be debated in the surgical literature[3–5]. In some countries the recent advent of laparoscopic antireflux surgery has led to a surge in surgery for gastro-oesophageal reflux, with many centres now reporting the early results of large series[6–8]. The careful documentation of outcome from this new approach has provided an opportunity critically to reassess surgical techniques for the treatment of gastro-oesophageal reflux disease.

The Nissen procedure is associated with a small but important incidence of troublesome dysphagia[1], and some surgeons now prefer to perform a partial fundoplication for all patients. Early reports describe good short-term results with the partial approach, and they suggest that the rate of postoperative dysphagia may be lower[8,9]. However, long-term efficacy is less well documented. This study was undertaken using a porcine model to compare the adequacy of the antireflux mechanism produced by Nissen fundoplication against that produced by two partial fundoplication variants (anterior and posterior). All operations were performed laparoscopically.

The results of these three types of fundoplication undertaken in an *ex vivo* model have been reported previously[10]. Somewhat surprisingly, all three operations (i.e. anterior partial fundoplication, posterior partial fundoplication and total fundoplication) raised lower oesophageal sphincter pressure and acted effectively as an antireflux barrier. However, the artificial nature of the *ex vivo* model is obvious and this study was undertaken to examine the same operations *in vivo*.

Materials and methods

Fifteen domestic White pigs underwent laparoscopic antireflux surgery and postoperative evaluation. Following preliminary oesophageal myotomy, the pigs were randomly allocated to undergo either an anterior, posterior or total fundoplication (five in each group), with the operation performed by a surgeon experienced in laparoscopic antireflux surgery. Manometric evaluation was undertaken during the initial surgery, and subsequently 2 weeks after operation in all animals. Several animals also had 4- and 6-week postoperative studies. Fundoplication 'yield' studies were performed concurrently. Animals were treated in accordance with the Australian Code of Practice for the Care and Use of Animals for Scientific Purposes, and ethical approval for this study was granted by the Animal Ethics Committees of the University of Adelaide and the Institute of Medical and Veterinary Science, Adelaide, South Australia.

General operative procedure

After commencing general anaesthesia, access to the oesophageal lumen was achieved by the preliminary placement of an oesophagostomy cannula into the cervical oesophagus through a left neck incision. A purpose-built T-shaped plastic cannula 1 cm in diameter with arms 2 cm long was used, with the intra-oesophageal portion forming an open half circle when viewed in cross-section. This provided direct access to the oesophageal lumen, without obstructing the passage of swallowed liquids or solids.

Preliminary oesophageal manometry was performed to determine the baseline lower oesophageal sphincter pressure. An eight-lumen water-perfused manometry catheter incorporating a sleeve sensor (Dent Sleeve, Adelaide, South Australia) was passed through the oesophagostomy and then distally into the stomach. The position of the lower oesophageal sphincter was determined by gradually withdrawing the catheter and noting pressure changes as each sensor passed through the gastro-oesophageal junction. The catheter was then positioned so that

Paper accepted 6 November 1997

the midpoint of the sleeve sensor was sited at the midpoint of the high-pressure zone. Resting lower oesophageal sphincter pressure was then measured over a 5-min period using the sleeve sensor. To eliminate the effect of intra-abdominal pressure, the basal end-expiration intragastric pressure was subtracted from that of the lower sphincter pressure to determine the resting lower oesophageal sphincter pressure.

Abdominal insufflation commenced following insertion of a Veress needle 2 cm above the umbilicus. Four laparoscopic ports were placed: 11-mm ports at the site of Veress needle insertion and in the left upper quadrant, and 5-mm ports in the epigastrium and left flank. A rigid curved instrument 4 mm in diameter was pushed through the abdominal wall of the right upper quadrant, and used to facilitate liver retraction, and to elevate the oesophagus following initial mobilization.

The oesophageal hiatus was dissected with laparoscopic scissors, and a distal oesophageal myotomy performed. This was extended approximately 1 cm on to the anterior wall of the stomach and 5 cm proximally, to divide the lower oesophageal sphincter completely. The pneumoperitoneum was then released and the lower oesophageal sphincter pressure was re-evaluated manometrically, to confirm complete sphincter ablation. This ensured that the subsequent fundoplication was responsible for any antireflux barrier tested during postoperative studies. The pneumoperitoneum was re-established and the hiatus was repaired posteriorly using one or two 2/0 polypropylene sutures.

Anterior fundoplication

An anterior fundoplication was fashioned by suturing the anteromedial gastric fundus to the right lateral wall of the distal oesophagus and concurrently to the posterior hiatal repair and right hiatal pillar with four or five interrupted sutures. The repair anchored a length of oesophagus within the abdomen, accentuated the angle of His, and fashioned a loose anterior 180° fundoplication.

Posterior fundoplication

To create a posterior fundoplication, the anteromedial fundal wall was drawn loosely behind the oesophagus and sutured to the anteromedial oesophageal wall with three sutures. A second row of three sutures secured the anterior fundus to the anterolateral oesophageal wall, fashioning a 270° posterior fundoplication, and leaving a strip of uncovered oesophagus 1 cm wide anteriorly, including the myotomized section.

Total fundoplication

A loose Nissen (circumferential) fundoplication 1·5–2 cm long was fashioned from the anterior wall of the fundus. It was secured by three sutures, which each included the oesophagus as well as the two pieces of stomach. An instrument was passed between the oesophagus and the fundoplication at the completion of the procedure to test that the fundoplication was not tight.

The pneumoperitoneum was then released and the lower oesophageal sphincter pressure was re-evaluated. The left upper quadrant port wound was extended to 4 cm in length, and the anterior gastric wall delivered. A flanged gastrostomy cannula 3 cm long and 1·5 cm in diameter was placed through an anterior gastrotomy and secured with a purse-string suture. This provided access to the gastric lumen for postoperative studies.

Postoperative studies

Postoperative studies were scheduled to take place at 2, 4 and 6 weeks after surgery. Sedation with ketamine was necessary to prevent discomfort from passage of the oesophageal manometry catheter and gastric distension. The manometric resting pressure generated by the fundoplication was determined using the sleeve sensor in the same fashion as in the preoperative studies. The catheter was then withdrawn and replaced by an 18-Fr nasogastric tube, with its tip sited 5 cm above the manometric high-pressure zone. A 24-Fr Foley catheter was passed into the gastric lumen through the gastrostomy cannula, and the catheter balloon was inflated to seal the gastrostomy. Competence of the gastro-oesphageal junction was assessed by infusing blue-coloured water into the gastric lumen. At the same time, the oesophageal tube was aspirated by a low-pressure suction device. Infusion continued until either blue water appeared in the oesophagostomy aspirate or the intragastric volume reached 2000 ml. The integrity of the gastro-oesophageal junction during progressive gastric distension was determined and the volume of intragastric fluid infused was recorded. No tube or measuring device crossed the gastro-oesophageal junction during these studies.

Statistical analysis

All data are presented as median (95 per cent confidence interval). Data sets were analysed using one-way analysis of variance to compare outcomes following anterior, posterior and total fundoplication.

Results

Fifteen domestic White pigs underwent the operation and subsequent postoperative studies. All pigs underwent studies 2 weeks after operation. Ten pigs were studied at the planned postoperative intervals during the 6-week study. The remaining five pigs were killed by barbiturate overdose between 2 and 5 weeks following surgery to avoid suffering from problems they developed from either the gastric or oesophageal cannulas. Three of these pigs underwent a Nissen fundoplication and two a posterior partial fundoplication. None of the problems encountered in these five animals was associated with the type of fundoplication performed. No difficulties with the intake of either oral fluids or solids were encountered in any animal.

The duration of surgery and the associated intraoperative studies was similar for each fundoplication variant (all median 120 min; $P = 0{\cdot}93$). The preoperative weights were similar for each group (anterior and Nissen fundoplication groups 20 kg, posterior fundoplication group 22 kg; $P = 0{\cdot}90$), as were the weights at the conclusion of the postoperative studies (anterior and Nissen 25 kg, posterior 27 kg; $P = 0{\cdot}65$). All animals resumed oral liquid and solid intake at similar time intervals, irrespective of the fundoplication type, with liquids tolerated within 24 h of surgery and solids resumed a day later.

The pressures measured manometrically in the lower oesophageal sphincter region are summarized in *Table 1*.

Table 1 Lower oesophageal sphincter pressures

	Lower oesophageal sphincter pressure (mmHg)			
	Anterior	Posterior	Total (Nissen)	P*
Before operation	10 (− 3 to 30)	19 (6–33)	25 (1–54)	0·33
After myotomy	0 (0–0)	0 (0–0)	0 (0–0)	
After operation	10 (8–19)	14 (11–43)	14 (13–21)	0·067
Week 2	12 (9–13)	14 (4–16)	10 (4–16)	0·17
Final study	14 (9–20)	13 (7–22)	8 (2–15)	0·13

Values are median (95 per cent confidence interval). *One-way analysis of variance

Before oesophageal myotomy, a pressure ranging from 4 to 50 mmHg was measured at the gastro-oesophageal junction. In all instances, the subsequent distal oesophageal myotomy abolished this high-pressure zone. Subsequently, each fundoplication variant generated a significant rise in the intraluminal pressure measured at the gastro-oesophageal junction. The postfundoplication intraoperative measurement was lowest in the anterior fundoplication group, although this difference was not significant. The pressures recorded 2 weeks following surgery for each fundoplication variant were similar. Similarly, when the final lower oesophageal sphincter pressures recorded from each animal were analysed, the median pressures were similar, although a trend towards lower pressure following Nissen fundoplication was seen. Transient lower oesophageal sphincter relaxation events were not identified during any of the postoperative studies.

Two weeks after surgery, all of the anterior and posterior fundoplications and four of the five total fundoplications remained fully competent to the intragastric infusion of up to 2000 ml water. The Nissen fundoplication which yielded to gastric distension became incompetent following the infusion of 360 ml fluid. At 4 weeks all of the Nissen (two pigs) and posterior (three) fundoplications tested were fully competent. One of the five anterior fundoplications became incompetent following the infusion of 1300 ml. Two anterior and one posterior fundoplications yielded to the infusion of liquid 6 weeks after surgery, with the volumes infused at the point of fundoplication yield ranging from 1200 to 1800 ml.

Discussion

Both short- and long-term outcomes following Nissen fundoplication have been reported extensively in the era of open surgery and have confirmed the status of the Nissen fundoplication as the 'gold standard' for antireflux surgery. Long-term success rates of approximately 90 per cent can be expected following this procedure[1], although most reports following both open and laparoscopic surgery confirm a small but significant incidence of troublesome postoperative dysphagia[1,11,12].

Partial fundoplication has been proposed both for routine antireflux surgery and for patients with manometrically proven oesophageal dysmotility, with uncontrolled studies suggesting that the incidence of adverse outcomes may be reduced[3,13]. However, improvements in outcome have not been confirmed by randomized trials[4,12]. One uncontrolled study suggests that higher resting lower oesophageal sphincter pressures occur following Nissen fundoplication compared with partial fundoplication[13], and within the subset of patients undergoing Nissen fundoplication it has been postulated that adverse outcomes are more likely in patients with higher postoperative lower oesophageal sphincter pressures[1]. However, the fact that anterior partial fundoplication is associated with a lower resting lower oesophageal sphincter pressure, yet still controls reflux, suggests that reflux control is not dependent on the measured postoperative resting sphincter pressure alone[3].

The present study assessed the influence of different fundoplication types using a model in which the lower oesophageal sphincter was ablated completely before performing an antireflux procedure. The intraoperative lower oesophageal sphincter pressures measured immediately after construction of the fundoplication were greater following both total and posterior fundoplication than after anterior partial fundoplication, although the failure to reach significance may reflect the numbers involved. These results are similar to those reported in previous open surgical randomized trials in humans. These differences disappeared over the passage of several weeks.

A variety of mechanisms has been proposed to explain how antireflux surgery works. These include changes in various mechanical parameters acting at the gastro-oesophageal junction due to alterations in anatomy following fundoplication[14] and restoration of an adequate length of intra-abdominal oesophagus[15], as well as effects due to hormonal stimulation of the intrinsic gastric muscle within the portion of stomach used to construct the fundoplication[16], and acceleration of gastric emptying[17]. These effects may all lead to a reduction in the prevalence of transient lower oesophageal sphincter relaxations, a phenomenon that has been demonstrated following Nissen fundoplication[18].

Similar outcomes to those of the present study were reported in a previous study using a similar protocol in abattoir-sourced porcine viscera[10]. Resting lower oesophageal sphincter pressures in the *ex vivo* viscera model after various types of fundoplication varied from 11 to 13·5 mmHg and competence at the gastro-oesophageal junction was restored in most instances. The resting lower oesophageal sphincter pressures were of a similar magnitude to those measured in the present study, suggesting that fundoplication-induced manometric increases in the lower oesophageal sphincter zone may be due, at least in part, to passive mechanical factors. A similar *ex vivo* study has been reported by Richardson *et al.*[19]. Both of these studies suggest that physical factors associated with fundoplication may play as strong or even a stronger role in reflux prevention than alterations in the physiology of the area. When the stomach in *ex vivo* preparation is filled with fluid, the fundoplication becomes distended before the rest of the stomach[10], and this distension impinges directly on the lower oesophagus. This may also explain why such fundoplications seem to be effective when placed in the chest[20].

This study has confirmed that all three variants of laparoscopic fundoplication restore adequate competence to the gastro-oesphageal junction and result in similar increases in postoperative lower oesophageal sphincter pressure. This provides support for the uncontrolled clinical outcome studies following laparoscopic partial fundoplication which describe good results after each type of fundoplication, and for the previous randomized trials which demonstrated little difference between posterior partial fundoplication and total fundoplication[4,12]. As this study demonstrates that the laparoscopic anterior partial fundoplication provides an effective antireflux barrier, and uncontrolled studies suggest that it is clinically effective, the authors have commenced further assessment of this procedure within a prospective randomized trial of laparoscopic anterior partial fundoplication *versus* total fundoplication.

Background The ideal method for staging tumours of the oesophagus and gastric cardia is not known. This paper was designed to assess the value of laparoscopy and laparoscopic ultrasonography in the staging of oesophageal and cardial carcinoma.

Methods From October 1993 to January 1996, 60 patients in whom no metastases were seen on gastroscopy, ultrasonography of the abdomen and supraclavicular region, helical computed tomography of the chest and abdomen or endosonography were scheduled for laparoscopy and laparoscopic ultrasonography.

Results Some 40 patients had carcinoma of the oesophagus, in one of whom liver metastases were found at laparoscopy and proven histologically. On laparoscopic ultrasonography metastases were found in four patients but were impossible to biopsy. These lymph node metastases were confirmed at exploratory laparotomy. Twenty patients had carcinoma of the gastric cardia; distant metastases were found in four at laparoscopy. On laparoscopic ultrasonography metastases were present in four further patients, all proven by biopsy.

Conclusion In this study laparoscopy was not an effective staging technique for oesophageal carcinoma. The inclusion of laparoscopic ultrasonography was of little benefit. A problem that was encountered was biopsy under laparoscopic guidance. In carcinoma of the gastric cardia, laparoscopy was more effective; adding laparoscopic ultrasonography doubled the number of patients seen to have metastatic disease.

In carcinoma of the oesophagus and cardia 60–80 per cent of patients are beyond cure at first presentation owing to widespread metastases or local irresectability of the tumour[1]. Thus, optimal preoperative staging is essential for selection of patients for curative resection. Despite the use of advanced imaging techniques such as endosonography and helical computed tomography (CT), metastatic spread or irresectability of the tumour is found in up to 20 per cent of patients during operation[2–8]. In particular, small liver metastases (less than 1 cm in diameter), lymph node metastases and peritoneal carcinomatosis are frequently encountered[3–8].

In recent years laparoscopy and laparoscopic ultrasonography have been used increasingly to stage abdominal malignancy. These techniques have proved to be highly successful in detecting liver, lymph node and peritoneal metastases in patients with pancreatic malignancy, with a sensitivity and specificity as high as 70–100 per cent[9–15].

The present study was performed to determine whether the combination of laparoscopy and laparoscopic ultrasonography is as effective in the staging of oesophageal and cardial carcinoma.

Patients and methods

From October 1993 to January 1996, 79 patients with biopsy-proven carcinoma of the oesophagus and/or cardia were referred for treatment. Distinction between tumours of the oesophagus and of the gastric cardia was made endoscopically by determining the hiatal impression and tumour bulk. The authors' service is a tertiary referral centre for patients with oesophageal and cardial carcinoma in the Netherlands. Thus, only patients considered potentially curable at other hospitals were referred. In this centre all patients are staged by means of the following techniques: gastroscopy, bronchoscopy in tumours of the upper and middle oesophagus, transcutaneous ultrasonography of the supraclavicular regions and abdomen (ATL HDI 3000; Bothell, Washington, DC, USA), contrast-enhanced helical CT of the chest and upper abdomen (100 ml Omnipaque 300, 2 ml/s; (Nycomed, Oslo, Norway); Envision CT injector (Medrad, Pittsburg, Pennsylvania, USA); collimation 8 mm, pitch 1·4, reconstruction increment 7 mm (Siemens, Erlangen, Germany)) and endosonography (GF-UM3, EU-M3; Olympus, Tokyo, Japan)[5–8]. Patients suspected of having distant metastases on the above-mentioned studies underwent biopsies to confirm metastases cytologically or histologically. Using these techniques about 70 per cent of patients referred to the authors' institution were finally subjected to surgery, 25 per cent were not operated on because of cytologically proven metastases and 5 per cent did not have surgery because of poor general condition[5]. In 19 cases distant metastases were proven and these patients were subsequently excluded from surgical treatment. Sixty patients had no metastases according to the above studies and were eligible for surgical resection. These patients were scheduled for staging by laparoscopy and laparoscopic ultrasonography.

Combined laparoscopy and laparoscopic ultrasonography was performed under general anaesthesia. A Hasson cannula was introduced in the subumbilical region. After pneumoperitoneum was obtained, a 10–12-mm cannula was inserted in the right and a 5-mm cannula in the left paramedian region under laparoscopic guidance. Laparoscopic staging included inspection of the peritoneum, greater omentum, diaphragm and liver capsule with a 0° telescope. Anatomical structures were manipulated with forceps inserted through the left paramedian port. If lesions suspect for metastases were found, a biopsy was taken to confirm the diagnosis histopathologically. In the absence

Paper accepted 9 December 1997

of suspect lesions a laparoscopic ultrasound probe was inserted through the right paramedian port. The convex array, multifrequency 5–7·5-MHz probe with a semiflexible tip and a total length of 45 cm and diameter of 9 mm (type 8555; Brühl and Kjaer, Naerum, Denmark) was covered by a sterile sheath containing a small amount of gel. The ultrasound transducer was connected to a diagnostic ultrasound monitor (type 3555; Brühl and Kjaer). To optimize anatomical insight, laparoscopic and ultrasonographic images were displayed together on a Sony 14-inch video monitor. Ultrasonographic inspection included the liver, coeliac trunk, greater visceral vessels and primary tumour if located intra-abdominally. Ultrasonography was performed by a radiologist and imaging findings were discussed with the surgeon. Whenever possible a biopsy under ultrasonographic guidance was taken of lesions suspected of distant metastases.

If distant metastases could not be proven cytologically or histologically, patients were scheduled for transhiatal oesophageal resection irrespective of the laparoscopic and ultrasonographic findings. Patients with proven distant metastases were referred for palliative non-surgical treatment.

The effectiveness of laparoscopy and laparoscopic ultrasonography was defined as the additional number of patients in whom distant metastases were found with these techniques and the number in whom these findings had therapeutic consequences (e.g. cytologically or histologically proven distant metastases). In addition, the sensitivity and specificity of laparoscopy and laparoscopic ultrasonography were calculated.

Results

Sixty consecutive patients, 54 men and six women with a mean age of 61·7 (range 43–79) years, were included in the study. Forty patients had carcinoma of the oesophagus (squamous cell carcinoma, 15; adenocarcinoma, 25); 14 of the adenocarcinomas had developed in a Barrett's oesophagus. Adenocarcinoma of the gastric cardia was present in 20 patients.

Carcinoma of the oesophagus

In one of the 40 patients with oesophageal carcinoma liver metastases were found at laparoscopy. These metastases were proven histologically and the patient was referred for palliative non-surgical treatment.

On laparoscopic ultrasonography distant coeliac lymph node metastases were found in five patients. One of these five patients also had biopsy-proven liver metastases at laparoscopy. In the remaining four patients cytological or histological proof could not be obtained, because it was not possible to biopsy the suspect lymph nodes. These four patients underwent operation at which coeliac lymph node metastases were confirmed histologically. As a result of these findings the patients did not undergo resection, but were treated palliatively.

Two of 35 patients without distant metastases on laparoscopy with laparoscopic ultrasonography nevertheless had distant metastases at laparotomy (false-negative rate two (5 per cent) of 40). There were no false-positive findings (e.g. no enlarged lymph nodes on laparoscopic ultrasonography that did not contain metastases on histopathological study). The sensitivity of the procedure was 0·70, the specificity 1·00.

Carcinoma of the gastric cardia

At laparoscopy distant metastases were found in four of 20 patients: peritoneal metastases in three and omental metastases in one. In all cases metastases were confirmed histologically.

On laparoscopic ultrasonography distant metastases were found in four further patients: liver metastases in two and coeliac lymph node metastases in two. In all cases these metastases were confirmed histologically (*Table 1*).

All eight patients with histologically proven metastases were excluded from further surgical resection and were referred for palliative treatment

In one of 12 patients without metastases at laparoscopy and laparoscopic ultrasonography, distant metastases were nevertheless found during exploratory laparotomy (false-negative rate one (5 per cent) of 20). The sensitivity of the procedure was 0·88, the specificity 1·00.

For the total study population of 60 patients the sensitivity was 0·81 and the specificity 1·00.

Discussion

This study shows that laparoscopy is not an effective staging technique in patients with oesophageal carcinoma who have undergone substantial non-invasive radiological staging. Distant metastases are found in only a minority of cases. In addition it is of little benefit to include laparoscopic ultrasonography. With the combination of laparoscopy and laparoscopic ultrasonography, the number of patients in whom distant metastases were found was small.

In the authors' institution patients with oesophageal carcinoma undergo extensive radiological staging including transcutaneous ultrasonography of the abdomen and supraclavicular region, helical CT and endosonography before they undergo operation. It can be expected that the number of patients with metastases on laparoscopy and laparoscopic ultrasonography will be higher in cases where radiological staging is not so extensive[15].

A problem encountered in the present study was to prove metastases histologically when they were suspected on laparoscopic ultrasonography. Often it was difficult to

Table 1 Distant metastases as determined by conventional staging, laparoscopy and laparoscopic ultrasonography

	Adenocarcinoma ($n = 25$)	Squamous carcinoma cell ($n = 15$)	Total for oesophagus ($n = 40$)	Carcinoma of the cardia ($n = 20$)	Overall total ($n = 60$)
Conventional staging	0	0	0	0	0
Laparoscopy	1	0	1	4	5
Laparoscopic ultrasonography	2	2	4	4	8
Sensitivity	0·60	1·00	0·70	0·88	0·81
Specificity	1·00	1·00	1·00	1·00	1·00

biopsy lesions under ultrasonographic guidance, owing to the angle under which biopsies had to be performed and the enlarged distance between a lesion and the abdominal wall as a result of the insufflation of gas.

Although there were no false-positive findings on laparoscopic ultrasonography in this study, it has been shown previously that, because of the limited specificity of radiological modalities, lesions suspected for distant metastases on these studies should be confirmed histologically when therapeutic consequences are being considered[5].

In carcinoma of the gastric cardia laparoscopy was more effective. In four of 20 patients distant metastases were shown by this technique. By adding laparoscopic ultrasonography the number of patients in whom distant metastases were diagnosed was doubled. Strikingly, distant metastases could be proven more frequently in patients with carcinoma of the cardia than in those with oesophageal carcinoma. This is due mainly to the fact that peritoneal metastases accounted for three of eight of the distant metasases found in patients with carcinoma of the cardia in this study and technically it is a simple procedure to perform biopsy of peritoneal lesions under laparoscopic guidance. Performing biopsies of mobile lymph nodes that are more deeply located in patients with oesophageal carcinoma is technically more demanding.

In this study the sensitivity and specificity of laparoscopy and laparoscopic ultrasonography were acceptable for both oesophageal and cardial carcinoma. The results are consistent with those of laparoscopy for gastric carcinoma as reported by Burke *et al.*[16].

A disadvantage of the technique is that patients are submitted to an operative diagnostic procedure under general anaesthesia. It is the authors' opinion that this disadvantage counts for little compared with the number of patients in whom a laparotomy can be averted. In addition there is a certain risk of tumour spill as a result of the procedure, although there are no valid numbers in the literature to assess the extent of this risk. However, the true incidence of tumour spill has to be determined in a larger study. In the present study port site metastases did not occur during the brief follow-up period of 30 months.

The conclusion of this study is that diagnostic laparoscopy with laparoscopic ultrasonography is of little value in the staging of oesophageal carcinoma. This is due mainly to the small number of patients in whom distant metastases are found and the difficulty of confirming these lesions histologically. There is a role for laparoscopy with laparoscopic ultrasonography when staging patients with carcinoma of the gastric cardia, although this needs to be determined more fully in larger series. The additional value of ultrasonography compared with laparoscopic inspection is limited by ultrasonographically guided biopsy techniques; to improve the efficacy of this procedure further, better biopsy techniques should be developed.

Controlled trial of preperitoneal local anaesthetic for reducing pain following laparoscopic hernia repair

G. T. DEANS, M. S. WILSON and W. A. BROUGH

Stockport Unit for Minimally Invasive Therapy, Stepping Hill Hospital, Stockport SK2 7JE, UK
Correspondence to: Mr G. T. Deans

Background A prospective randomized trial was performed to determine whether local anaesthetic solutions injected into the preperitoneal space may provide additional pain relief following transabdominal preperitoneal laparoscopic hernia repair.

Methods One hundred patients undergoing transabdominal preperitoneal laparoscopic hernia repair were allocated randomly to receive (1) bupivacaine 1·5 mg/kg, (2) bupivacaine 1·5 mg/kg with 1 in 200 000 adrenaline, (3) bupivacaine 3 mg/kg or (4) saline instilled into the preperitoneal space at the end of the operation. An independent clinical assessor determined the level of pain using a visual analogue pain score and noted the parenteral and oral analgesia requirements at 4, 8, 12 and 24 h after operation.

Results At each of the time intervals, there was no significant difference between the groups for pain scores (at 24 h, $P = 0·71$) or the number of doses of either morphine (at 24 h, $P = 0·73$) or oral analgesia (at 24 h, $P = 0·89$). There was also no significant difference in the time to return to normal activity or work between the groups.

Conclusion This study suggests that instilling local anaesthetic into the preperitoneal space has no significant effect on postoperative pain relief requirement following laparoscopic hernia repair. Other methods of reducing postoperative pain should be sought that may facilitate day-case laparoscopic hernia surgery.

Evidence suggests that laparoscopic hernia repair is associated with a more rapid rehabilitation than conventional open herniorrhaphy[1,2]. Yet, unlike its open counterpart, laparoscopic hernia repair is not widely performed as a day-case procedure in the UK[3]. This could be related to the management of postoperative pain as a requirement for regular parenteral analgesia would prevent patients from meeting the criteria on day-case surgery[4,5].

The use of local anaesthetic in the port sites[6] or peritoneal cavity[7–10] following laparoscopic procedures is not proven to reduce analgesia requirement. In laparoscopic hernia repair instilling local anaesthetic into the confined preperitoneal space may represent a novel method of increasing the effect of the local anaesthetic[11]. If this resulted in a significant reduction in postoperative analgesia requirement more surgeons may be persuaded to perform day-case laparoscopic hernia surgery.

A prospective clinical trial was therefore performed to determine whether the instillation of local anaesthetic into the preperitoneal space following laparoscopic hernia repair reduces postoperative pain.

Patients and methods

One hundred patients (94 men, six women; median age 64 (range 27–83) years, undergoing transabdominal preperitoneal laparoscopic hernia repair were randomly allocated to receive (1) bupivacaine 0·25 per cent plain at a concentration of 1·5 mg/kg ($n = 25$); (2) bupivacaine 0·25 per cent (1·5 mg/kg) with 1 in 200 000 adrenaline ($n = 25$); (3) bupivacaine 0·5 per cent plain (3 mg/kg) ($n = 24$); or (4) saline 0·9 per cent ($n = 26$). Only the scrub nurse knew the randomization code, the anaesthetist, surgeon and clinical assessor all being blind as to the solution injected.

All preparations were injected at the end of the operation into the completely re-closed preperitoneal space via an introducer inserted through a 5-mm port. The port sites were not injected with local anaesthetic. The validity of the technique had been verified previously[11]. Postoperative pain relief consisted of intramuscular morphine 10 mg or a combination of paracetamol 500 mg and codeine phosphate 30 mg (Tylex; Schwarz, Chesham, UK) two tablets orally as required. Rectal non-steroidal preparations were not used.

All patients underwent operation in the morning, were observed overnight and reviewed the following morning. Total analgesia requirements at 4, 8, 12 and 24 h of operation were determined for each patient. An independent clinical assessor determined the overall level of pain at these time intervals using the McGill visual analogue pain scale[11]. An attempt was made to assess the different components of the pain as port site, preperitoneal space or visceral. Statistical comparisons between groups were performed using χ^2 analysis.

Results

There was no significant difference between the groups with respect to age, sex, American Society of Anesthesiologists grade, grade of surgeon performing the operation, length of operation or postoperative complications. Although patients complained more of visceral discomfort than pain in either the port or hernia sites, attempts at accurately assessing the site of the pain proved unsuccessful as most patients found it difficult to accurately localize the pain in the early postoperative phase.

The median (range) doses of analgesia and pain scores for each of the groups at 24 h are shown in *Table 1*. The results at other time intervals were similar and are therefore not shown. At each of the time intervals there was no significant difference between the groups in the

---

Paper accepted 16 December 1997

Table 1 Analgesia requirement and pain scores 24 h after operation and instillation of local anaesthetic

Local anaesthetic solution	Doses of morphine	Doses of Tylex	Pain score
Bupivacaine 0·25 per cent, plain	0 (0–3)	2 (0–12)	4 (2–8)
Bupivacaine 0·25 per cent with adrenaline 0·25 per cent	0 (0–3)	2 (0–8)	3 (2–8)
Bupivacaine 0·5 per cent, plain	0 (0–4)	2 (2–24)	4 (1–8)
Saline 0·9 per cent	0 (0–3)	2 (0–12)	4 (1–8)
P	0·73	0·89	0·71
χ^2	8·7	18·2	17·0
d.f.	12	27	21

Values are median (range)

number of doses of morphine (at 24 h, χ^2 = 8·7, 12 d.f., P = 0·73) or Tylex (at 24 h, χ^2 = 18·2, 27 d.f., P = 0·89) or pain scores (χ^2 = 17·0, 21 d.f., P = 0·71). There was also no significant difference in the time to return to normal activity or work between the groups, and to date there have been no recurrences.

Discussion

In laparoscopic hernia repair the systemic absorption of bupivacaine inserted into the preperitoneal space is slight and well within the non-toxic range[11]. This suggests that the majority of the drug is rapidly bound locally to receptors in the preperitoneal space. Confining the local anaesthetic to the 'wound' caused by the preperitoneal dissection might theoretically result in the majority of the drug being fixed locally and a greater reduction in postoperative pain. However, the present study reveals that this local binding of bupivacaine does not significantly reduce the requirement for postoperative pain relief after laparoscopic hernia repair.

In open hernia repair the addition of adrenaline may enhance the analgesic effect of the local anaesthetic. The present study suggests that this is not so in the preperitoneal space following laparoscopic hernia repair, possibly because the systemic absorption of bupivacaine from this space is unaffected by adrenaline[11]. Similarly, increasing the concentration of bupivacaine to 0·5 per cent does not significantly reduce postoperative pain requirement.

The lack of benefit from local anaesthetic in this study may be related to postoperative pain following laparoscopic procedures being comprised of parietal, diaphragmatic and visceral components[9]. Although many surgeons try to reduce the parietal component by infiltrating local anaesthetics into the laparoscopic port sites, there is no evidence that this reduces postoperative pain[6]. In the present study, this manoeuvre was therefore not performed, as it would have interfered with assessment of the preperitoneal local anaesthetic. Previous studies have shown that free instillation of local anaesthetic into the peritoneal cavity after laparoscopic cholecystectomy[9,10] and tubal ligation[7,8] may reduce the diaphragmatic component without affecting the other two components. In this study preperitoneal bupivacaine may have reduced the parietal component without affecting either the diaphragmatic or visceral component.

The visceral component is caused by diffusion of carbon dioxide into the bowel[9,12]. The disappointing results from instilling local anaesthetic into either the port sites or peritoneal cavity following laparoscopic surgery may be due to the failure to eliminate this component of pain after laparoscopy[6–10]. In the present study patients complained more of visceral discomfort than pain in either the port or hernia sites. This might explain why using preperitoneal local anaesthetic alone had no significant effect on postoperative pain requirement.

It is likely that the reduction in pain after laparoscopy will require techniques that address a combination of the parietal, diaphragmatic and visceral components. Further studies, incorporating local anaesthetic injection of the port sites, laxatives or non-steroidal anti-inflammatory drugs, are therefore required to assess ways of reducing pain after laparoscopy. In the interim, the sole use of preperitoneal local anaesthetic has no significant effect on postoperative pain requirements following laparoscopic hernia repair and its routine use cannot be recommended.

Tracheobronchial lesions following oesophagectomy: prevalence, predisposing factors and outcome

Sir

I read with interest the recent paper by Bartels *et al.* (*Br J Surg* 1998; **85**: 403–6).

I am concerned about the frequent use of the term 'tracheobronchial fistula' in the text and legends. A fistula is an abnormal communication between the lumen of one viscus and the lumen of another[1]. Surely the lesions referred to in the article are pathological communications between the tracheobronchial tree and the mediastinum and/or the pleura.

Rationing and surgery: setting boundaries

Sir

Interesting points were raised about rationing in surgery in this leading article by Mr New (*Br J Surg* 1998; **85**: 291–2) and it was rightly stated that 'cosmetic surgery' is a poorly understood term. The article discussed the apparent triviality of procedures such as liposuction, breast reduction and rhinoplasty and their relevance in the NHS. In this context most aesthetic procedures such as those discussed are performed for psychological reasons *and* the physical benefit of the patient.

Breast reduction, for example, is helpful in reducing physical discomfort such as back and neck pain[1] and may facilitate breast cancer detection[2]. Liposuction is used in the treatment of conditions as diverse as gynaecomastia[3], lymphoedema[4], lipodystrophy, hemifacial atrophy[5], lipomas and the debulking of surgical flaps. Rhinoplasty can also provide functional improvement in breathing. It would, therefore, be helpful to discuss rationing in terms of the condition that is to be treated rather than the surgical procedure itself, i.e. the management of minimally ptotic breasts rather than breast reduction or mastopexy and the management of acquired contour deformities rather than liposuction.

This is still not a perfect solution, but this approach may prevent an existing trend in the NHS to ration procedures that may provide significant physical, functional and psychological benefit.

Genetic alterations in chronic pancreatitis: evidence for early occurrence of *p53* but not K-*ras* mutations

Sir

I read with interest the paper by Gansauge *et al.* (*Br J Surg* 1998; **85**: 337–40) regarding the absence of K-*ras* mutations in chronic pancreatitis. The differential diagnosis of chronic pancreatitis and pancreatic cancer can still present problems in certain patients. It can be particularly difficult to detect a carcinoma within pre-existing chronic pancreatitis. The risk of developing pancreatic cancer is said to be higher in patients with chronic pancreatitis[1] and it is therefore of potential practical importance to be able to detect changes of neoplasia in such patients. If K-*ras* mutations were absent in chronic pancreatitis this may prove a useful tool as the mutation is present in 75 per cent[2] to 90 per cent[3] of pancreatic ductal adenocarcinomas. One of the series quoted by the authors is that of Van Laethem *et al.*[4], but this group have, more recently, published a report of K-*ras* mutation in 19 of 76 (25 per cent) patients with chronic pancreatitis[5]. This important finding needs clarification since patients with chronic pancreatitis may represent those at high risk of developing pancreatic cancer, although the proportion is obviously higher than one would expect.

Bile duct injury during laparoscopic cholecystectomy without operative cholangiography

Sir
We read with interest the prospective audit of bile duct injury during laparoscopic cholecystectomy by Wright and Wellwood (*Br J Surg* 1998; 85: 191–4). The authors' conclusion, that operative cholangiography is not necessary for the safe performance of laparoscopic cholecystectomy, might have been all the more meaningful if cholangiography had actually been undertaken and been demonstrated to be of no benefit. Few surgeons would suport the view that operative cholangiography provides any safeguard against ductal injury as it is no substitute for adequate exposure of the junction of Hartmann's pouch and the cystic duct. There is some evidence to suggest that operative cholangiography may limit the extent of bile duct injury by early detection and avoid exposing the patient to biliary peritonitis.

Routine operative cholangiography enables the surgeon to better interpret all forms of cholangiography. *Fig. 3* is said to reveal a fistulous communication to a right accessory duct but appears to demonstrate an injury to the main right hepatic duct. It is not clear why the authors believe that an operative cholangiogram would not have detected the entry of the cystic duct into or near the right hepatic duct. They were fortunate that the resulting biliary fistula resolved without apparent further complication 3 years after surgery. Of some 40 patients referred for management of bile duct injury to Edinburgh Royal Infirmary over the past 9 years, we have observed one such patient whose isolated right ductal injury was similarly missed at cholecystectomy (without operative cholangiogram). Two subsequent laparotomies culminated in suture ligation of the free end of the divided 'accessory' duct without a cholangiogram. This patient was referred more than 4 years following this last procedure with recurrent episodes of sepsis within the obstructed right duct system and required treatment by means of a right hepatectomy. Such cases serve to underline the importance of early recognition and appropriate management of bile duct injury.

Author's reply

Sir
I am grateful to Mr Wakefield and Professors Bornman and Garden for their comments. The authors comment that *Fig. 3* indicates that the main right hepatic duct was divided during laparoscopic cholecystectomy. The postoperative endoscopic retrograde cholangiopancreatography (ERCP) was submitted as part of the original paper but the paper was deemed too long and this figure removed. In fact, when we noted that this small duct had been divided we performed a laparotomy and ligated the cut end having carried out an operative cholangiogram which revealed a normal duct pattern with no evidence of any leakage of bile. Several days later when a fistula became apparent ERCP revealed no evidence of contrast leak and that the right main hepatic duct was intact.

We agree that had this been the right main hepatic duct spontaneous closure would have been very unlikely and much larger volumes of bile would have been produced from the fistula. One possibility is that the accessory duct did, in fact, communicate with the right duct system but that this could not be shown on operative cholangiography or ERCP. The duct that was divided was a small accessory duct and the right hepatic duct system was demonstrated after the injury to be intact both on operative cholangiography during laparotomy and on subsequent ERCP.

Genetic predisposition to breast cancer

Sir
We read with interest the leading article by Mr Odling-Smee (*Br J Surg* 1998; **85**: 147–8) and share his desire for a common management strategy for women at increased risk of breast cancer. The suggested protocol for the management of such women however leaves much to be desired. The sensitivity of annual mammography is reduced in women under 50 years with a family history of breast cancer[1] and annual mammography in these women does not lead to a diagnosis of earlier stage breast cancer than respective a priori risk groups[2]. No clinical trial of mammography has demonstrated a reduction in breast cancer mortality for these women and the cost implications to the NHS of regular screening would be enormous[3]. Monthly self-examination results in the detection of increased numbers of small and node-negative tumours[4,5], but no study has shown an improvement in survival. Regular examination by an experienced clinician has similarly poor results[5,6]. Many screening centres struggle to meet current demands and a large increase in the screened population would take these centres past breaking point. Strategies for breast cancer prophylaxis (including long-term tamoxifen and retinoid supplementation) are the subject of clinical trials but no data have yet been published to support their use in high-risk women.

As the purse-strings of the NHS tighten, it is unacceptable to institute 'hypothetical' and 'empirical' protocols for patient management and the only acceptable long-term management of such women currently is within the boundaries of a randomized clinical trial.

Author's reply

Sir
I do not disagree with Messrs Byrne and Bundred and was careful to keep away from the financial issue. I have proposed

the development of a common management strategy and the national collection of data but the details are open to discussion. All those who run breast clinics see large numbers of patients referred by GPs for advice about family history. Such is the public demand for this advice that if breast clinics do not provide it someone else will. We can either refuse to see these patients because breast clinics are not funded or we can develop a common strategy and collect information nationally and press for appropriate funding. I would advocate the latter.

Systemic inflammatory response syndrome

Sir

We congratulate Davies and Hagen on their clear and complete review (*Br J Surg* 1997; **84**: 920–35) of systemic inflammatory response syndrome (SIRS). We write to stimulate discussion regarding the statement 'No directed therapies have been successful to date in influencing outcome' which seems true regarding mediator therapies. We suggest that directed therapy for oedema is a frequently overlooked opportunity.

Oedema that is both general and organ-specific does influence outcome. Oedema after reperfusion injury kills muscle in the calf due to compartment syndrome. Oedema of the brain follows head injury. Oedema within kidney parenchyma responds to decapsulation with restoration of function[1]. Oedema after septic shock complicates recovery.

True, '... secondary MODS [multiple organ dysfunction syndrome] develops ... as a consequence of host response'[2], but physician response is also a factor. Shock requires rapid vascular filling with fluids biased toward the cells and starches that stay in leaky capillaries. Aftershock calls for different fluids and the goal changes from vascular filling to reducing extracellular overfill quickly while preventing new shock.

The following recent developments should increase the interest in oedema and capillary leak. Urine microalbumin parallels general leak and now accurately predicts pulmonary failure and the end of leak[1] as a guide to albumin use. Oedema sharply decreases when a starch stops the leak of albumin from capillaries, probably by plugging pores. The starch used has molecules of medium size and a narrow range of molecular weights. Using this starch, reperfused spinal cords retain function as oedema is controlled[3] and heart muscle survival rate improves 500 per cent after reperfusion[4,5]. Also, vitamin C reduces postburn oedema[6]. For these reasons the existing paradigm of SIRS as a mediator problem only might well be extended to include the renewed consideration of oedema itself in the aggravation and management of SIRS and clinical capillary leak syndrome (CCLS).

Authors' reply

Sir

The letter by Dr Bascom and colleagues addresses the possibility of modulating the secondary event of tissue oedema which is a sequel to SIRS. Oedema, as illustrated by the various examples cited by the authors, is a manifestation of the loss of integrity within the microcirculation. This is the result of activation of the SIRS cascade of cellular and humoral mediators. The therapeutic interventions suggested by Dr Bascom and colleagues suffer the same weaknesses as those described in our article for mediator modulation. The development of SIRS and secondary MODS are driven by the host's response to the initiating stimulus; the physician generally is playing catch-up in a clinical rollercoaster whose ride is more often than not poorly defined, and any therapies used are aimed at treating effects and not causes. Therefore, we continue to contend that cellular and humoral mediators are primary movers in the pathophysiology of SIRS and would categorize tissue oedema as a consequence of SIRS-induced microcirculatory derangements.

Randomized clinical trial of conventional cholecystectomy *versus* minicholecystectomy

Letter 1

Sir

Although it is interesting to compare the two approaches in a prospective randomized trial (*Br J Surg* 1997; **84**: 1683–6) the design is unusual and the study raises other issues. The authors state that (in February 1997) there had been only one study comparing mini- and laparoscopic cholecystectomy, when there have been three major trials in the UK alone[1–3]. We were surprised to learn that 'under the present German national health system patients undergoing such operations are required to have a minimum stay in hospital of 11 days'. If this is so, it largely negates any attempt to shorten hospital stay by improving surgical techniques. The purpose of the study was to compare pain but, surely, it is unethical to allow patients after straightforward operations to have severe pain or even moderate pain. It is not stated whether local anaesthetic was infiltrated in the wounds. Moss[4] has shown that with good local infiltration 99 per cent of patients having an open cholecystectomy do not need opiates. Ortega *et al.*[5] found that with good analgesia patients with traditional open procedures went home at a median of 1·1 days compared with 1·3 days for laparoscopic procedures. In our own randomized trial comparing mini- and laparoscopic procedures, the patients experienced mild or no pain after operation[6].

It is very difficult to see how the authors can conclude that 'minicholecystectomy cannot be regarded as a true alternative to the superior laparoscopic technique' when they have not compared the two or even reviewed the existing trials.

Letter 2

Sir

The clinical trial by Schmitz *et al.* comparing mini- and conventional cholecystectomy led to a conclusion that 'minicholecystectomy cannot be regarded as a true alternative to the superior laparoscopic technique'. This is illogical as laparoscopic cholecystectomy was not included in this study.

In minilaparotomy, the length and the location of the incision should be defined. Since 1990, we have performed micro- and minilaparotomy cholecystectomy in 2012 unselected patients. Some 92·5 per cent had a 4-cm single microlaparotomy incision[1,2], 7·1 per cent had a 6-cm minilaparotomy, and 0·2 per cent had an 8-cm classic minilaparotomy incision. Four patients had a 'classic' cholecystectomy.

In a randomized study of 270 patients in each arm, postoperative pain and ambulation was compared in laparoscopic cholecystectomy *versus* microlaparotomy cholecystectomy and no significant difference was found[4].

In our international courses, we teach that the short incision, its location and specific instrumentation contribute to decreased pain, quicker recovery and reduced cost. Schmitz *et al.* use a subcostal incision transecting muscles involved in respiration thereby creating excessive pain. The 4-cm vertical midline incision at the lower edge of infrasternal triangle provides reduced pain and better exposure[3,5].

In the 2012 patients, common duct injury occurred in only three patients. The mean operating time in 512 simple procedures was 18 min, and in 1500 complicated procedures, 35 min.

We observed no haematoma and consider low-dose heparin contraindicated. Sequential compression stockings may be used. Three patients (0·014 per cent) died within 30 days.

Letter 3

Sir

Schmitz *et al.* suggest that minicholecystectomy cannot be considered as an alternative to laparoscopic cholecystectomy. They compared minicholecystectomy, not with laparoscopic cholecystectomy but, surprisingly, with open cholecystectomy, which weakens the argument. A parametric statistical test (Student's *t* test) was used to compare differences in visual analogue scale (VAS) scores for pain instead of a non-parametric method suitable for an ordinal scale. More serious is that the pain scores were grouped into slight, moderate and severe, and thereafter the tests were made within these groups. This makes the differences between the two types of operation smaller. The graphs in *Figs 1* and *2* are deceptive as a large difference in VAS scores between groups could still lead to graphs that show no difference. Additionally, how can the mean VAS score for patients with severe pain undergoing minicholecystectomy be 6·46 and 6·29 respectively when severe pain is defined as a VAS score between 7 and 10?

Finally, *Fig. 3* suggests that open cholecystectomy is associated with more pain than minicholecystectomy as for each postoperative day the analgesia requirement is greater for the open cholecystectomy group. Instead of comparing the total analgesia requirement for the two groups, the authors studied each postoperative day separately. With only 65 patients in each group the power to find any significant difference by such an approach is very low. No significant difference certainly does not mean that the two groups are necessarily equal. The conclusions drawn by the authors are not justifiable from the study.

Authors' reply

Sir

The aim of our study was to evaluate the amount of analgesic medication required by patients after minicholecystectomy or conventional cholecystectomy. It showed that the group of patients undergoing minicholecystectomy were free from pain after the operation 2 days earlier (i.e. slight pain, VAS between 0 and 3) as compared with the group of patients undergoing conventional cholecystectomy. The comparison of the total analgesia requirement for both groups did not show any significant difference. Furthermore, it was not the authors' intention to compare the results of the minicholecystectomy group with the results of any laparoscopically cholecystectomized group of patients.

Rozsos *et al.* in their comment try to compare their own results with this study. It has to be recognized that they cholecystectomize patients through a vertical midline incision, which is not a common practice and requires specially designed instruments for this procedure to prevent long incisions. While their data concerning this procedure might be of interest they cannot be used because of the above-mentioned circumstances in a comparative assessment of the results of our study.

Johnson and Majeed mention three randomized studies comparing laparoscopic cholecystectomy with minicholecystectomy. Our study did not intend to make a direct comparison between mini- and laparoscopic cholecystectomy. Rather the principal interest was to determine which of the open cholecystectomies should be considered as a standard technique. The results attained from this standard procedure can then be rightfully compared with those of laparoscopic cholecystectomy. The standard procedure would also be the defined interchange operation.

In our opinion it is not useful to refer to randomized studies that do not focus on the value of minicholecystectomy. In many randomized studies the advantages of preoperatively applied low-dose heparin could be demonstrated, lowering the rate of deep vein thrombosis, especially after general anaesthesia. Furthermore, the *Deutsche Gesellschaft für Chirurgie* strongly recommends heparinization before abdominal procedures. It is therefore incorrect to ignore this high standard, especially during a randomized study as suggested in Rozsos *et al.*'s commentary.

The analgesic medication used by patients consisted of paracetamol *ad libitum*, and was sufficient to lower the perceived level of pain to a minimum. Concerning postoperative pain the superiority of laparoscopic cholecystectomy has to be mentioned as many randomized studies could demonstrate lower pain levels after laparoscopic cholecystectomy compared with other techniques.

The day of discharge for the patient is very often used in studies as an argument for or against an operative procedure. To register the complications occurring after operation for scientific reasons the patient has to be observed for at least 14 days.

The perceived level of pain, its treatment, different health insurance systems, different cost structures and the patient's will influence and decide the day of discharge today in Germany. The influence of the operative procedure on the actual day of discharge has a secondary role. It was therefore important for this study and possible to monitor all patients for 10 days. The perceived level of pain was measured with the VAS. Slight pain was defined as 0 to 3, moderate pain as 3 to 6 and severe pain as 6 to 10 on the VAS, and not 7 to 10 which was a misprint in our study. We thank Dr Iselius for recognizing this anomaly.

Book reviews

Textbook of Surgery. The Biological Basis of Modern Surgical Practice. 15th ed. (CD-ROM – Single User Version)

D. C. Sabiston Jr (ed.). 1998. Philadelphia, Pennsylvania: WB Saunders. £110.

'Sabiston' is one of the standard surgical textbooks and it was a pleasure to explore it using this new format. The disk is essentially an on-screen version of the book, with appropriate indexing, searching and linkage software to enable rapid access throughout the text. There are no additional features of content, however, which seems to be an opportunity missed. This disk is certainly among the front runners for the CD-ROM market being a direct competitor to the *Oxford Textbook of Surgery*. Reference libraries (institutional or departmental) with appropriate access terminals and accumulating a CD-ROM section will probably have both disks. Individual surgeons will probably choose one or other product. The text is easy to read and up to date. The search and indexing systems work well, enabling rapid access to appropriate sections of text, and it is possible to highlight and print sections of text and tables. I was disappointed not to be able to download illustrations. I enjoyed looking at this disk and will certainly return to it when searching for up-to-date reference material outside my specialist field of interest

Trauma

I. Greaves, J. M. Ryan and K. M. Porter (eds). 245 × 188 mm. Pp. 421. Illustrated. 1997. London: Arnold. £47.50.

This is the first volume in what intends to be a series covering topics 'across the whole spectrum of trauma' which the Editors hope 'will allow people to remain up to date outside their own particular field of specialist expertise'. The editors are British and the editorial and advisory boards are composed of 'traumatologists' from around the world. Only seven of the 58 contributors to this volume, however, work outside the UK. The book has 11 sections and 36 short chapters covering a wide spectrum of trauma-related topics, such as air safety, disaster mitigation, prehospital analgesia, paramedic training, what constitutes a trauma surgeon, emergency and definitive care, rehabilitation and land mines. The style of the book is refreshing and easy to read. Chapter 16 on hypotensive resuscitation is superb and the brief historical notes on Colles (the fracture) and Thomas (the splint) are excellent. Only British doctors could write a chapter on 'Doctor in . . . acting'; only they would understand it. This is entertaining and valuable reading for anyone involved in the care of patients with trauma, be it doctors, nurses or paramedics. The authors succeeded in what they set out to do; one would only hope that the next volumes include more international contributors.

Imaging of Anorectal Diseases

S. M. Hussain (ed.). 333 × 213 mm. Pp. 148. Illustrated. 1997. London: Greenwich Medical Media. £69.50.

Imaging of Anorectal Diseases is a beautiful book. It contains good pictures of magnetic resonance imaging (MRI) scans, endosonographs and proctographs. It also gives a helpful overview of diagrams to explain the pictures. The first three chapters give an impression of the normal anatomy of the anorectum depicted with various imaging techniques. MRI with endoanal and endorectal coils, as well as endosonographs, give very good pictures of anatomy and pathological findings. The only problem is that one has to disturb the normal anatomy by introducing an endoanal device. Probably new developments with phased-array and surface coils will give even more accurate anatomical images. The findings with anal fistulas, perineal Crohn's disease and tumours are convincing. In two chapters the authors outline the place of radiological imaging techniques in detecting causes of faecal incontinence and other functional disorders. This book is of great value for colorectal surgeons and is a guideline for radiologists dealing with anorectal disorders. In a comprehensive way it gives information that cannot be found in general textbooks.

Surgical Management of Cutaneous Ulcers and Pressure Sores

B. Y. Lee and B. L. Herz (eds). 260 × 180 mm. Pp. 263. Illustrated. 1997. New York: Chapman and Hall. £65.

Recognition of the disability and cost to health care systems of patients with ulcers has spurred renewed interest in the management of these conditions. This tends to be a multispecialty and multiprofessional problem involving both the community and hospitals. There have been very few good publications in this area bringing together all the aspects of care of these patients. As such, this book makes a welcome addition. Contributions from 21 authors, all based in North America, cover an enormous range of topics, including the biology of wound healing and the role of nutrition, aspects of nursing care, and assessment of pressure ulcers as well as specialized plastic surgical procedures. Much of the clinical practice and health economics are based on American experience, but this does not greatly diminish its interest to a European reader. A large part of the book relates to pressure ulcers and these sections are well worth reading. Probably due to breadth of ground covered, and despite the title, I found it hard to understand at whom the book was aimed. Some subjects, such as the biology of wound healing and fasciotomy of the diabetic foot, are covered in great detail, while others, in particular the management of patients with arterial disease, were brief to the point of being of little value. It would have been helpful to have had a more uniform level of knowledge throughout the book. Similarly, there tends to be a lot of repetition between contributors. For instance, the aetiology of venous ulceration is discussed on at least three separate occasions. In summary, anyone involved in the care of patients with ulcers will find something of interest in this volume. However, I think the wide variation in the level of knowledge presented limits its value, making it neither a specialized handbook nor a broad overview.

Hepatobiliary and Pancreatic Surgery. Imaging Strategies and Surgical Decision Making

S. R. T. Evans and S. M. Ascher (eds). 260 × 183 mm. Pp. 569. Illustrated. 1998. New York: Wiley-Liss. £100.

In the past two decades major developments in both surgery and imaging procedures for hepatobiliary and pancreatic diseases have been made. For a hepatobiliary and pancreatic surgeon it is essential to understand the advantages and disadvantages of each of the different imaging studies. This book, written by American radiologists and surgeons, is a hybrid medical text between the two specialties with reviews for the anatomic sections. It is divided into four main anatomic sections: gallbladder, biliary tree, liver and pancreas. Each section is subdivided into different chapters that focus on the different imaging techniques. Even new imaging studies, such as MRCP, are described and explained extensively; these chapters are written by radiologists. Every chapter finishes with a surgical summary, written by surgeons.

In each of the subtitled chapters different disorders are featured. First, epidemiological data are presented, followed by thorough discussion of advantages and disadvantages of the imaging technique in question. The surgical summary gives a good idea what a surgeon needs to consider and which technique is most helpful to obtain the necessary information. The practitioner is directed through the assessment of patients with specific diseases by the help of flow diagrams. This is one of the reasons why this book is especially useful not only for experienced hepatobiliary and pancreatic surgeons but also for residents and junior practitioners. The volume is well illustrated with an ample number of black and white illustrations. Numerous original pictures are explained; helpful sketches are added. This book is aimed at hepatobiliary and pancreatic surgeons at every educational level. With its detailed descriptions it may be a stimulus even for experienced surgeons to consider special indications for imaging studies in their patients. In times of restrained financial resources it is even more important to reduce unnecessary and expensive diagnostic tests. The diagnostic investigation as suggested in this book will certainly help to render diagnostic strategies more efficient and then more cost-effective. This detailed and well illustrated book should become an every-day tool in the assessment of patients with hepatobiliary and pancreatic disorders.

Scientific Surgery

The British Journal of Surgery is committed to practice of surgery based on scientific evidence. Each month we will publish a list of randomized trials and meta-analyses collated from English language publications. A collection of all these papers will be available in the Scientific Surgery Archive which will be held on *The British Journal of Surgery* website together with links to free Medline sites where the full papers can be accessed (see below for details). If you have published a recent randomized trial which has not been featured in Scientific Surgery, the Editors would be pleased to receive a reprint and consider its inclusion.

Randomized trials

Mishihira T, Hirayama K, Mori S. A prospective randomised trial of extended cervical and superior mediastinal lymphadenectomy for carcinoma of the thoracic esophagus.
Am J Surg 1998; **175**: 47–51. (UGI-oesophagus)
A study of 62 patients in which 2- and 5-year survival rates were not significantly different.

Benedetti E, Coady MT, Asolati M, Dunn T, Stormoen B, Bartholomew A *et al.* A prospective randomised clinical trial of perioperative treatment with octreotide in pancreatic transplantation.
Am J Surg 1998; **175**: 14–17. (UGI-pancreas)
Octreotide significantly reduced the overall rate of major complications from three of seven to zero of ten untreated patients.

Staubach K-H, Schroder J, Stuber F, Gehrke K, Traumann E, Zabel P. Effect of pentoxifylline in severe sepsis: results of a randomized, double-blind, placebo-controlled study.
Arch Surg 1998; **133**: 94–100. (General)
Fifty-one intensive care patients were studied. Pentoxifylline significantly improved cardiopulmonary dysfunction but had no effect on survival.

Shackford SR, Bourguignon PR, Wald SL, Rogers FB, Osler TM, Clark DE. Hypertonic saline resuscitation of patients with head injury: a prospective, randomized clinical trial.
J Trauma 1998; **44**: 50–8. (General)
Hypertonic saline used instead of Ringer's lactate did not affect outcome in this study of 34 patients.

Miller PR, Meredith JW, Chang MC. Randomized, prospective comparison of increased preload *versus* inotropes in the resuscitation of trauma patients: effects on cardiopulmonary function and visceral perfusion.
J Trauma 1998; **44**: 107–11. (General)
Visceral perfusion was improved in patients managed by increasing fluid preload; the study involved 39 patients.

Carapeti EA, Kamm MA, McDonald PJ, Phillips RKS. Double blind randomised controlled trial of effect of metronidazole on pain after day-case haemorrhoidectomy.
Lancet 1998; **351**: 169–72. (LGI-anus)
In this trial including 40 patients, postoperative metronidazole 400 mg three times daily for 7 days reduced pain significantly on days 5–7 after surgery, increased patient satisfaction and allowed earlier return to work.

Rhodes M, Sussman L, Cohen L, Lewis MP. Randomised trial of laparoscopic exploration of common bile duct *versus* postoperative endoscopic retrograde cholangiography for common bile duct stones.
Lancet 1998; **351**: 159–61. (UGI-biliary)
Eighty patients with bile duct stones identified during laparoscopic cholecystectomy were randomized: primary duct clearance was achieved in 75 per cent of each group.

Hanna GB, Shimi SM, Cuschieri A. Randomised study of influence of two-dimensional *versus* three-dimensional imaging on performance of laparoscopic cholecystectomy.
Lancet 1998; **351**: 248–51. (UGI-biliary)
No advantage found for 3-D imaging by specialist registrars doing 80 operations.

Younes RN, Yin KC, Amino CJ, Itinosche M, Rocha-e-Silva M, Birolini D. Use of pentastarch solution in the treatment of patients with haemorrhagic hypovolaemia: a randomized phase II study in the emergency room.
World J Surg 1998; **22**: 2–5. (General)
In this study of 23 patients, pentastarch was as effective as isotonic saline.

Robeer GC, Brandsma JW, van den Heuvel SP, Smit B, Oostendorp RAB, Wittens CHA. Exercise therapy for intermittent claudication: a review of the quality of randomised trials and evaluation of predictive factors.
Eur J Vasc Endovasc Surg 1998; **15**: 36–43. (Vascular)
Ten studies were evaluated, all showed the significant benefit of exercise.

The British Journal of Surgery website can be found at: http://www.bjs.co.uk. In addition to details of current and previous articles featured in Scientific Surgery, the website contains details of the Editorial Team and Board, instructions to prospective authors, links to other sites (such as The Cochrane Library) and forthcoming surgical events. The Editors welcome comments and suggestions about our website, either in writing or through the website address.

Instructions to authors

The British Journal of Surgery publishes original articles, reviews and leading articles. All manuscripts are submitted to editorial review.

An article is reviewed for publication on the understanding that the work it reports has not been submitted simultaneously to another journal, has not been accepted for publication elsewhere and has not already been published. **Any detected attempt at dual publication will lead to automatic rejection and may prejudice acceptance of future submissions.** To avoid subsequent embarrassment, please submit with your manuscript copies of any other papers, either published, in press, or submitted for consideration elsewhere, which relate to the same subject. It is essential that you submit any other publications or submissions using the same data set to the Editors to allow assessment of any potential overlap with the submission to the Journal. Indicate on the title page whether the paper is based on a previous communication to a society or other meeting. Articles and their illustrations become the property of the Journal unless rights are reserved before publication.

Send four copies of original articles and other editorial matter to: The Editor, *The British Journal of Surgery*, Blackwell Science Ltd, 25 John Street, London WC1N 2BL, UK. Telephone: 0171 404 1831. Facsimile: 0171 404 1927. Books for review should be sent to the same address.

A covering letter must accompany all submissions and must be signed by all authors. State in the covering letter whether an abstract of the work has been published and give an appropriate reference on the title page. Disclose in the covering letter any potential or actual personal, political or financial interest you may have in the material, information or techniques described in the paper. The decision to publish or withhold such information will be made by the Editors. Acknowledge all sources of financial support for the work. The first named author is responsible for ensuring that all authors have seen and approved the manuscript and are fully conversant with its contents. The Journal accepts the criteria for authorship proposed in the *British Medical Journal* (*BMJ* 1994; **308**: 39–42). When a paper has many authors (i.e. more than six), you may be asked to justify the inclusion of all names listed. Results of multicentre studies should be reported under the name of the organizing study group. Methods of recognizing contributors have been proposed (*Lancet* 1995; **345**: 668).

Disks

Following final approval of articles, you will be asked to submit the accepted version on disk. These should be IBM-compatible. An accurate hard copy must accompany each disk, together with details of the type of computer used, software, and disk system if known. **Do not justify.** Please send us digital versions of your figures. Ideally, these should be sent in native format or WMF if created in Windows. Files saved as PS, EPS, GIF and TIF may also be used, but please note that it may not be possible to modify them. Avoid using tints if possible; if they are essential, try to make them coarse. Further details can be obtained from the publisher. Disks will not be returned to authors.

Rejected manuscripts and illustrations will not normally be returned.

Ethics

The Journal publishes all material relating to human investigation and animal experiments on the understanding that the design of the work has been approved by local ethics committees or that it conforms to standards currently applied in the country of origin. The Journal further reserves the right not to publish an article on the grounds that appropriate ethical or experimental standards have not been reached. Written consent must be obtained from the patient, legal guardian or executor for publication in *The British Journal of Surgery* of any details or photographs that might identify an individual. Submit evidence of such consent with the manuscript.

Preparation of manuscripts

The British Journal of Surgery subscribes to the policy of uniform requirements for manuscripts, which is designed to permit authors to resubmit papers to journals without extensive recasting. Authors are advised to consult the *New England Journal of Medicine* 1997; **336**: 309–15, or to obtain the leaflet 'Uniform Requirements for Manuscripts Submitted to Biomedical Journals' from The Editor, *British Medical Journal*, BMA House, Tavistock Square, London WC1H 9JR, UK (cost £1.00 per copy).

Authors are responsible for the accuracy of their report including all statistical calculations and drug doses. **When quoting specific materials, equipment and proprietary drugs, state in parentheses the brief name and address of the manufacturer.** Failure to do so will result in delay in publication as the Journal believes that this information is essential for any reader who wishes to obtain similar material. Generic names should normally be used.

Original articles

Original articles should normally be in the format of introduction, methods, results, discussion. Each manuscript must have a 200-word structured abstract. Lengthy manuscripts are likely to be returned for shortening. The discussion in particular should be clear and concise and should be limited to matters arising directly from the results. Avoid discursive speculation. **Randomized clinical trials** should be clearly identified as such in the title and abstract.

Reviews

The Editorial Board of *The British Journal of Surgery* encourages submission of review articles on topics of interest to its readers. Any topic will be considered, but priority will be given to those addressing a major current problem. The author of each accepted review will receive an honorarium. Potential authors are advised to contact: Mr J. A. Murie, University Department of Surgery, The Royal Infirmary, Edinburgh EH3 9YW, UK.

Leading articles

The Editors commission signed leading articles which are 600–900 words in length and address controversial topics of current interest. They should be supported by no more than ten key references. Submissions may be subjected to external review and assessment by the Editorial Board before acceptance. The Editors retain the right to alter style and shorten material for publication. An honorarium is payable on publication.

Correspondence

The Editors welcome topical correspondence relating to articles published in the Journal. Letters should not exceed 250 words and should be typed double-spaced.

Typescripts

Manuscripts must be clearly reproduced with adequate space for editorial notes. **Type or print the text on one side of sheets of A4 paper (210 × 297 mm) with double spacing and 4-cm margins. Manuscripts that do not conform to these requirements will be returned to you for recasting.** Begin each section (abstract, introduction, patients and methods, results, and discussion) on a new page.

Title page

On the title page give: (1) the title of the article; (2) the name and initials of each author; (3) the department and institution to which the work should be attributed; (4) the name, address, and telephone, facsimile and e-mail numbers of the author responsible for correspondence and to whom requests for reprints should be addressed; (5) sources of financial support; and (6) the category in which the manuscript is being submitted (original article, review etc.).

Abstract

This should be not more than 200 words on the second page of the manuscript and be presented in a structured format. **Background:** state why the study was done, and its main aim; **Method:** describe patients, laboratory material and other methods used. Clearly identify the nature of the study: randomized controlled trial, retrospective review, experimental study, etc. **Results:** state the main findings of the study; include important numerical values. **Conclusion:** state the main conclusion drawn from the results. Controversial or unexpected observations may be highlighted, but keep this section brief. Write the abstract in clear prose.

Tables and illustrations

Submit three copies of all illustrations and tables. Type each table on a separate page with an appropriate brief title. Line drawings are acceptable as clear black on white graphics, computer printout or photocopies. Submit radiographs, photomicrographs, etc unmounted in the form of glossy prints, original transparencies or negatives. If you include photocopies, they should be of sufficient quality to enable the Journal's referees to judge their content and value. Label each illustration on the reverse side giving its number (to correspond with its reference in the text) and the name(s) of the author(s); indicate the top of the illustration. Include a measure of magnification of photomicrographs. Illustrations should be drawn and labelled appropriately for reduction to one or two column widths of the Journal. Include explanations of symbols and shading in the legend. Survival curves should be accompanied by a table giving the actual numbers of patients involved. Include in the legends to illustrations and the footnotes to tables brief but comprehensive explanations of all the information presented. Look at recent issues of the Journal for examples of accepted layout. If a table or an illustration has been reproduced from a published work give the original source in full. Obtain permission to use published work from the original author and the publisher before submission.

Abbreviations

Use abbreviations sparingly. Terms that are mentioned frequently may be abbreviated but only if this does not impair comprehension by the reader. Use abbreviations consistently throughout the text and clearly define each one on first use.

Numbers and units

Use the decimal point, not a comma, e.g. 5·7. Use a space and not a comma after thousands and multiples thereof, e.g. 10 000. Use SI units (International System of Units) except for the measurement of blood pressure (mmHg). Where measurements were made in non-SI units, give the actual values and units, with SI equivalents inserted in parentheses at appropriate points.

Statistics

For detailed guidance on the handling of statistical material, consult *Br J Surg* 1991; **78**: 782–4. In evaluating a manuscript the Editors and statistical referees will consider the design of the study, the presentation and analysis of data and the interpretation of results.

Design

Set out clearly the objectives of the study, identify the primary and secondary hypotheses, and the chosen end-points, and explain the rationale for the choice of sample size. Investigators embarking on randomized controlled studies may wish to consider the CONSORT statement (*JAMA* 1996; **276**: 637–9).

Presentation

Whenever possible use graphical presentation to illustrate the main findings of a study. The use of standard deviation and standard error should be clearly distinguished. Do not use the '±' symbol; these statistics should be presented in parentheses after the mean value.

Analysis

Clearly describe which methods were used for which analyses; any methods not in common usage should be supported by references. Report results of statistical tests by stating the value of the test statistic, the number of degrees of freedom and the *P* value, e.g. '$t = 1·34$, 16 d.f., $P = 0·20$'.

Actual *P* values should be reported to two decimal places, especially when the result is not significant, rather than stating 'not significant'. Whenever possible, the results of the primary analyses should be reported using confidence intervals instead of, or in addition to, *P* values.

Interpretation

Do not confuse statistical significance with clinical significance. In particular, 'negative' findings should be interpreted through the use of confidence intervals.

Beware of placing undue emphasis on secondary analyses, especially when they are suggested by an inspection of the data.

References

Type the references with double spacing in the Vancouver style (see above: Uniform Requirements for Manuscripts Submitted to Biomedical Journals). Reference to abstracts from meetings is discouraged. Reference to unpublished communications will not be accepted. Cite personal communications in the text, in parentheses. The first author is responsible for confirming the acceptability of the material quoted with the originator.

In the text, number the references consecutively by superscript: ^{1} or $^{1-3}$. References cited only in tables or figures should be numbered in sequence according to the first mention of the table or figure in the text. The sequence for a standard journal article should be: author(s); title of paper; journal name abbreviated as in Index Medicus (written in full if no abbreviation is quoted); year of publication; volume number; page numbers. For example: De Bolla AR, Obeid ML. Mortality in acute pancreatitis. *Ann R Coll Surg Engl* 1984; **66**: 184–6. The sequence for the chapters of a book should be: author(s); chapter title; editors; book title; place of publication; publisher; year of publication; page numbers. For example: Calenoff L, Rogers L. Esophageal complications of surgery and lifesaving procedures. In: Meyers M, Ghahremani G, eds. *Iatrogenic Gastrointestinal Complications*. New York: Springer, 1981: 123–63.

British Journal of Surgery 1998, **85**, 1025–1026

Role of lymphadenectomy in the treatment of differentiated thyroid carcinomas

Papillary thyroid cancer (PTC) is the most common form of thyroid carcinoma. It has a comparatively good prognosis and, therefore, before conclusions can be drawn about the merit of any particular operation, patients must be followed over decades. Surgical complications have carried great weight in the discussion about how radical the surgical treatment should be, but complications nowadays are rare. The discussion of whether total thyroidectomy or lesser procedures should be the treatment for thyroid carcinomas was protracted. Now, reasonable agreement exists that total or near-total thyroidectomy is the best treatment and the focus of the discussion has moved to the treatment of node metastases. The disagreement concerning the treatment of node metastases is pronounced when it comes to PTC.

The argument supporting a radical approach to node excision is that the presence of node metastases lowers the survival rate. Advocates for a conservative approach think that little association exists between node metastases and death from thyroid carcinoma. Both factions base risk calculations on the node status *before* operation. If it is presumed that the presence of lymph node metastases is a risk factor for death, then a radical node dissection would attenuate or abolish the association between the occurrence of preoperative node metastases and premature death. If less radical operations are done, a smaller proportion of the patients with lymph node metastases will have these diagnosed which makes a fair calculation of the risk of preoperative lymph node metastases impossible. Basing the risk calculation on the incidence of node metastases left after operation would be more logical, if it were possible. To obtain an unequivocal answer to the question of whether a reduction of node metastases makes a difference to outcome would require a randomized study. If such a study were possible, it would take more than a decade to provide the answer.

The only currently available method is to compare survival in patients who are similar in all aspects other than the treatment of node metastases. Two such Scandinavian studies exist. In one, node-picking was the procedure used to treat node metastases[1,2]. In the other, a meticulous node dissection of the central neck region was performed in 90 per cent of patients and a lateral neck dissection only if macroscopic lateral node metastases were found[3]. In the node-picking series 8 per cent of the patients were excluded from the analysis because they were not radically treated, the death rate was 9 per cent and the recurrence rate was 23 per cent after a median observation of 7·3 years[2]. In the other series[3] the results were updated in March 1998 when the death rate was 2 per cent and the recurrence rate was 6 per cent after a median observation of 15·6 years.

In 1988 there was a recommendation that patients in whom residual tumour remained after resection should not be included in the calculation of recurrence rate[4]. Many groups have subsequently excluded this kind of patient from survival analyses[2,5]. No distinction exists between persistent and recurrent disease. If this kind of exclusion were accepted, subjective influence on the analysis would be introduced, making comparisons between patient series difficult or impossible. Exclusion of patients with distant metastases would be appropriate when evaluating the results of local therapy.

Grant *et al.*[4] defined local recurrence of PTC as tumour in the resected thyroid bed, thyroid remnant or other adjacent tissues of the neck. Lymph node metastases were classified as a separate entity. Fifty per cent of their patients with local recurrence died from PTC. According to these authors very few patients die from PTC when neck nodal metastases represent the first recurrence. The tumour tissue in a node metastasis can grow and destroy the typical lymph node histology, leading pathologists to think that separating a node metastasis from other local recurrences can be impossible. This means that node metastases can cause more deaths than is apparent when the patients are grouped according to the scheme of Grant *et al.*[4].

Sporadic medullary thyroid carcinoma (MTC) is usually unilateral while hereditary MTC has a bilateral distribution. Node metastases from MTC have deleterious effects on survival[6]. Both central and lateral node metastases usually occur in patients with palpable MTC, while patients with non-palpable hereditary MTC with few exceptions have only central node metastases. Most agree that total thyroidectomy and central lymph node dissection should be carried out for this condition. The handling of the lateral node metastases should be based on their known distribution[7,8].

Following this scheme for primary treatment of patients with MTC, the result for 50 patients with hereditary MTC, 60 per cent of whom had node metastases, was one death during a mean observation of 15 years. Meticulous extended lymphadenectomy has been used also in patients with persistent and recurrent MTC with normalization of calcitonin levels in one-third of the patients and with a substantial reduction in another 40 per cent of patients. In some patients with pain or diarrhoea the use of this technique has resulted in resolution of symptoms[9,10].

The meticulous surgical technique that has been effective in reducing or normalizing the tumour marker, calcitonin, in MTC[9,10] has been applied to PTC with excellent results[3]. The author's experience and most arguments speak in favour of total thyroidectomy and a meticulous central neck dissection as the treatment of choice for PTC. The central dissection is done because most lymph node metastases occur in that area. Central metastases are most detrimental for survival and there is a greater risk of complications at repeat operations in the central area. There is no need for a routine lateral dissection in PTC.

Intra-abdominal hypertension and the abdominal compartment syndrome

As long ago as 1951 M. G. Baggot, an anaesthetist from Dublin, suggested that forcing distended bowel back into an abdominal cavity of limited size may kill the patient[1]. He had conceived that the factor leading to the high mortality rate associated with abdominal wound dehiscence is not the dehiscence itself but the emergency procedure to correct it that produces intra-abdominal hypertension (IAH). But even then Baggot may have been re-inventing the wheel as the adverse physiological effects of IAH have been repeatedly described since the 19th century[2]. These reports, as well as more recent studies documenting the respiratory[3], haemodynamic[4] and renal[5] compromise caused by IAH, were largely ignored by the surgical community. The 1990s, however, generated a large number of experimental and clinical studies to promote the notion that IAH, resulting in an abdominal compartment syndrome (ACS), is a common and clinically significant entity in critically ill surgical and traumatized patients[6].

An increase in the volume of any of the abdominal or retroperitoneal contents increases intra-abdominal pressure (IAP) which, at the bedside, is best measured via a urinary bladder catheter connected to a manometer or pressure transducer. As IAP is transmitted to adjacent spaces and cavities, it adversely affects cardiac output, pulmonary ventilation, renal function and cerebrospinal pressure. Furthermore, increased IAP is associated with a reduction in visceral perfusion; a strong correlation has been found between increasing IAP and a decrease in splanchnic blood flow, as shown by a reduction in intramucosal pH of the gut[7].

Deleterious consequences of raised IAP appear gradually. At pressures of less than 10 mmHg, cardiac output and blood pressure are normal but visceral arterial blood flow falls significantly; an IAP of 15 mmHg produces adverse cardiovascular changes, and an IAP of 20 mmHg may cause renal dysfunction and oliguria, while an increase to 40 mmHg induces anuria. In an individual patient, the effects of increased IAP are not isolated but usually superimposed on multiple underlying and coexistent factors, the most notable being hypovolaemia, which aggravates the effects of increased IAP. ACS consists of increased inspiratory pressures, decreased cardiac output and oliguria, in spite of apparently 'normal' or increased cardiac filling pressures[8]; it is observed in patients with an IAP above 25 mmHg.

Clinically significant IAH has been observed in a variety of contexts, such as postoperative intra-abdominal haemorrhage, complicated abdominal vascular procedures, operations such as hepatic transplantation, severe abdominal trauma (accompanied by visceral swelling, haematoma or the use of abdominal packs), severe peritonitis, acute pancreatitis, the use of a pneumatic antishock garment, peritoneal insufflation during laparoscopic procedures and tense ascites in patients with cirrhosis[6,7]. The liberal measurement of IAP allows the recognition of IAH with increasing frequency in daily clinical practice. Cardiovascular collapse or respiratory failure in patients with an abdominal catastrophe, previously attributed to septic shock, hypovolaemia or premorbidity compromised organ systems, may now occasionally be explained by the coexistence of IAH. In most instances the adverse effects of IAH cannot be separated from the underlying disease. Is the patient with intestinal obstruction and an IAP of 25 mmHg moribund because of hypovolaemia, endotoxaemia or IAH? Probably all of these work in concert and need to be addressed.

That extreme cases of ACS require immediate attention is obvious. But what about moderate increases in IAP compensated by appropriate fluid and ventilatory therapy? A prospective study has identified IAP over 20 mmHg in a third of patients who are undergoing abdominal surgery. Postoperative IAH correlates significantly with the incidence of renal dysfunction and death[9]. The authors believe that the detrimental physiological effects of IAH take place long before the manifestation of ACS becomes clinically evident, just as nerve and muscle ischaemia begins long before neuromuscular signs of the extremity compartment syndrome are evident. In our experience, IAH is common after major abdominal trauma. It may cause gut mucosal acidosis at lower bladder pressures, long before the onset of clinical ACS. Uncorrected, it may lead to splanchnic hypoperfusion, distant organ failure and death. Prophylactic non-closure of the abdomen may aid the prevention, early recognition and treatment of IAH, and reduce these complications[10].

Clinically significant IAH resulting in an ACS should be managed by abdominal decompression. However, the decision to decompress the abdomen should not be based on isolated measurements of IAP without considering the whole clinical circumstance. Early or mild physiological abnormalities caused by increased IAP can be altered by fluid administration or afterload reduction. Decompression in established ACS, however, restores normal physiology when performed in the well resuscitated patient. To prevent haemodynamic decompensation, intravascular volume should be restored, oxygen delivery maximized, and hypothermia and coagulation defects corrected. Following decompression, the abdominal skin and fascial edges are left open, using one of the temporary abdominal closure methods that have been described[6].

The key issue, however, is prevention. To avoid IAH and ACS, forceful closure of the abdomen in patients with massive retroperitoneal haematoma, visceral oedema, severe intra-abdominal infection or a need for haemostatic packing should be avoided. Postoperative evisceration is a sign of IAH and managing it with fascial reclosure under tension is a recipe for a high morbidity rate. Intraoperative measurement of IAP, with the fascial edges temporarily approximated, provides an indication of whether formal abdominal closure is advisable.

That severe IAH is harmful and needs to be addressed is indisputable, but is limited IAH a marker of critical surgical illness or significant co-morbidity? Longitudinal studies of a large number of surgical and traumatized patients are needed to allow a better understanding of the natural history and clinically significant effects of mild and moderately raised IAP before routine decompression for non-dramatic IAH can be recommended. Meanwhile this old-new pathophysiological entity, which has been ignored for so long, should be recognized, prevented and treated.

Review

Physiological and functional outcome following ultra-low anterior resection with colon pouch–anal anastomosis

N. WILLIAMS and F. SEOW-CHOEN

Background Low rectal cancer is usually managed by ultra-low anterior resection (ULAR) with total mesorectal excision and straight coloanal anastomosis. However, following this procedure patients often suffer from frequency, urgency of bowel action and, occasionally, faecal incontinence. To overcome such problems, a colon pouch may be fashioned and a subsequent colon pouch–anal anastomosis performed. The physiological and functional outcome following the use of a colon pouch are appraised.

Methods All relevant papers identified from a Medline search and papers from cross-referencing were reviewed.

Results and Conclusion Creation of a colon pouch following ULAR results in reduced bowel frequency, and a lower incidence of urgency and faecal incontinence. Although there is a slightly increased incidence of evacuatory disorder and need for enemas or suppositories, this appears to be a minor problem which may possibly be overcome by using a smaller colon pouch. Compared with straight coloanal anastomosis following ULAR, the creation of a colon pouch produced a superior functional outcome.

Rectal cancer remains one of the commonest cancers in many countries; in the UK it is the second commonest malignancy after lung cancer. For many decades surgical thinking and practice was dominated by the teaching of Sir Ernest Miles[1,2] which, for middle and low rectal cancers, meant abdominoperineal resection (APR) of the rectum with a permanent colostomy. Surgical practice has changed dramatically since Miles' time. Most patients undergoing potentially curative resection now have restoration of intestinal continuity and preservation of the anal sphincter by means of an ultra-low anterior resection (ULAR). The term 'ULAR' is applied if the rectal dissection proceeds below the pelvic floor or the rectum is excised completely.

This change in surgical practice has been the consequence of several factors. First, distal intramural spread of cancer used to be a major consideration when planning curative resection and early studies suggested that the distal clearance margin should be at least 5 cm[3–5]. However, more recent studies suggest that distal intramural spread rarely exceeds 1 cm[6–9], and that cases where spread exceeds 1 cm are usually associated with advanced disease with multiple lymph node metastases[10,11]. Distal intramural spread may carry little prognostic significance in determining local recurrence of rectal cancer; overall prognosis may, possibly, be a function of incurable disease at presentation[12,13]. The necessity of total mesorectal excision for these low rectal cancers is now widely accepted[14,15]. Second, the development of stapling devices has enabled anastomoses to be constructed easily within the depths of the pelvis[16–18]. Third, following low anterior resection with total mesorectal excision local recurrence rates have not increased. Local recurrence is not significantly different to that following APR of the rectum[19–21]. Fourth, there is a lower morbidity and complication rate following low anterior resection than that following APR[22,23]. Finally, several studies have demonstrated no increased perioperative or postoperative mortality rate associated with anterior resection compared to that of APR[22–25]. Thus, for carcinoma of the middle and lower third of the rectum, a sphincter-saving operation has become the procedure of choice[26–29].

Functional outcome following ultra-low anterior resection

The major advantage of ULAR compared with APR is the avoidance of a colostomy. This is assumed to be more acceptable to patients and to result in a better quality of life[30]. Certainly it avoids the high psychological morbidity associated with a permanent abdominal stoma[31–33]. A consequence of rectal excision, however, is a greatly reduced reservoir capacity and an alteration in pelvic physiology following reconstruction with a straight coloanal anastomosis. The functional outcome of this is that 5–60 per cent of patients experience disorders of continence, ranging from the inadvertent and uncontrolled passage of flatus to frank faecal incontinence[34–42].

Maintenance of continence depends on a complex neurophysiological integration of the rectum with the anal canal. Within the anal canal the internal anal sphincter (IAS) is thought to be one of the major determinants of the maintenance of continence. The IAS exists in a state of tonic contraction[43], providing the main contribution to the resting pressure which may be measured within the anal canal[44]. It is able to relax in a reflex coordinated manner in response to rectal distension and this is considered to be the physiological basis for the rectoanal inhibitory reflex (RAIR)[45]. As intrarectal pressure increases, there is a transient decrease in pressure in the

Paper accepted 16 February 1998

upper part of the anal canal, therefore reducing the pressure gradient and allowing rectal content to come into contact with the richly innervated mucosa (the so-called anal transitional zone). This process, known as sampling, is thought to be the basis of distinguishing whether there is faeces or flatus in the anal canal, permitting appropriate action as socially convenient.

It was initially assumed that continence would be maintained provided the IAS and pelvic floor skeletal musculature remained intact[46,47]. However, the clinical outcome following ULAR is rather different, with patients often suffering increased bowel frequency, urgency of defaecation and minor faecal leakage (anterior resection syndrome)[39,48–50]. So what are the underlying physiological abnormalities following ULAR and how do they explain this functional outcome? Several studies have demonstrated a significant reduction in anal canal mean resting pressure (MRP)[50–52] after anterior resection, although this finding is by no means universal[35,40,53]. Such a fall in MRP has been ascribed to the dilatation of the IAS produced by the stapling gun used for the anastomosis and, interestingly, IAS damage can be detected by endoanal ultrasonography after insertion of the stapler into the rectal remnant[54]. A similar fall in MRP is encountered after transanal endoscopic microsurgery in which the operating sigmoidoscope (external diameter 4 cm) is the cause of anal dilatation[55–57]. Another possible explanation for the fall in MRP after ULAR is damage to the nerve supply of the IAS. The IAS has a dual autonomic innervation, receiving a sympathetic contribution from L1/L2 via the hypogastric nerves and a parasympathetic contribution via the pelvic nerves[58,59]. To investigate the cause of a reduced MRP, Horgan *et al.*[52] performed intraoperative manometric studies in patients undergoing anterior resection for rectal cancer. Following inferior mesenteric artery ligation, there was no change in anal canal MRP. By contrast, following insertion of the stapling device there was a reduction in anal canal MRP. While passage of the stapling device is an unavoidable aspect of ULAR, pelvic nerve damage is a surgeon-dependent variable and may be one area that could be improved[51].

Studies examining the effect of low anterior resection on anal canal maximum squeeze pressure (MSP) from a voluntary effort have produced conflicting results with both a decrease[51] and no significant change[35,39] reported. The external anal sphincter is innervated by the pudendal nerves and it is unlikely that surgical damage to this innervation is the explanation for any decrease in pressure. Surgical trauma to the pelvic floor may, however, be a contributory factor.

The presence or absence of the RAIR continues to be a source of much debate. Based on its mechanism of action, it is easy to understand why many researchers feel this reflex to be of such importance. In a prospective study of ULAR with anorectal physiological evaluation 3 months later, Jehle *et al.*[51] found the reflex was abolished in all 55 patients. Pedersen *et al.*[35] reported that two of 12 patients had a positive RAIR after surgery, although they also noted that seven of the 12 had no RAIR before operation. By contrast, Lewis *et al.*[39] found in patients studied at a median of 13 (range 4–100) months following anterior resection for rectal cancer, that all 34 had a RAIR present. Similarly, and from the same institution, Miller *et al.*[41] detected a positive RAIR in all 30 patients examined at a median of 11 (range 1–96) months after anterior resection. One possible explanation for these differing findings is that of continuing physiological adaptation of the 'neorectum'; this seems likely when one examines the time-scale of these studies. RAIR is more likely to be present as time from operation increases, a reflection of the re-establishment of traumatized neural pathways.

Perhaps the most illuminating recent studies examining the reasons for poor clinical outcome after anterior resection have been those that have directly compared patients with a good result with those with a poor result. In one such study, 19 of 30 patients were deemed to have a poor functional outcome[41]. The sensory threshold of the anal canal mucosa was greater in the upper anal canal (i.e. less sensitive) in those with a poor outcome. Distension of the neorectum resulted in the virtual abolition of the pressure gradient between the upper and lower part of the anal sphincter, such that neorectal pressure exceeded anal canal pressure, the result being an episode of incontinence. In another study, 44 (60 per cent) of 73 patients had disturbance of bowel function following anterior resection[40]. Physiological evaluation revealed that variables such as MRP and MSP were no different between the two patient groups. However, stressing the sphincter mechanism by rectal distension demonstrated differing responses between the groups. In those with a poor outcome, maximum sphincter inhibition occurred at lower distension volumes and, consequently, rectal pressure was greater than at any point along the anal canal. The pressure differential that is noted in the sampling reflex appeared to be lost in patients with a poor outcome. The volume of neorectal distension necessary to elicit such profound sphincteric inhibition was found to correlate with the degree of clinical dysfunction.

The influence of the length of residual rectal stump continues to be a source of debate[51] although most authors agree that it plays a role in determining functional outcome following ULAR[34,36,39,40,49,60]. Jehle *et al.*[51] found that length of rectal stump did not influence outcome in 55 patients when examined 3 months after operation. However, this physiological evaluation was made early in the postoperative period, at a time which is considered by many to be the adaptation phase[61].

Many patients suffer from varying degrees of faecal incontinence. The mechanism underlying this dysfunction is clearly complex, but it probably involves an interplay of poor IAS function secondary to the trauma of pelvic dissection and anal dilatation. Coupled to this is reduced compliance, i.e. diminished capacity for receptive relaxation. The rationale for the creation of a colonic pouch appears attractive. Not only may it increase reservoir capacity, it may also act as a 'pressure sump'[41], in which the high intraluminal pressures generated within the relatively non-compliant colon, are dissipated before reaching the anal canal and overcoming the sphincter mechanism.

Colonic J pouch

The creation of a reservoir to aid bowel function was initially used, in the form of an ileal pouch reservoir, after total colectomy[62,63]. The colon pouch was first reported in 1986, simultaneously in this Journal by Lazorthes *et al.*[64] from Toulouse and Parc *et al.*[65] from Paris. Lazorthes *et al.* described a series of 65 patients, 45 of whom had a straight coloanal anastomosis following ULAR. In the remaining 20 a colonic J pouch was fashioned, a 6-cm pouch in 14 and a 12-cm pouch in six. The most dramatic finding was a significantly reduced bowel frequency in patients with a colonic reservoir compared with those with a straight anastomosis. Physiological evaluation suggested that threshold volume (i.e. degree of rectal distension to elicit first sensation) and maximum tolerable volume were significantly greater in patients with a colon pouch than in those with a straight coloanal anastomosis. They also found an inverse relationship between bowel frequency and maximum tolerable volume of the neorectum. Follow-up after 1 year revealed that 86 per cent of patients with a colon pouch had a bowel frequency of less than 3 per day, compared with only 33 per cent of patients with a straight anastomosis[64]. The series from Parc *et al.*[65] using an 8-cm colon pouch, was equally impressive in restoring bowel function and continence. This series, however, contained the first suggestion of a potential drawback of the colonic reservoir, namely inadequate evacuation. Twenty-five per cent of patients required suppositories on alternative days to help evacuation of the colon pouch[66].

In a similar study of colon pouch *versus* straight coloanal anastomosis following ULAR, Nicholls *et al.*[67] found that ten of 13 and six of nine patients respectively had perfect continence at a median of 7 (range 3–15) months after restoration of pouch function by closure of the defunctioning stoma. Frequency of defaecation was significantly less in those with a colon pouch. Although only one of 13 patients with a pouch in this series required suppositories to aid evacuation, videoproctography suggested incomplete evacuation in three of nine studies by this technique. Kusunoka *et al.*[68] commenced a randomized trial to examine functional outcome of ULAR with or without a colonic pouch but abandoned it before completion because of the apparent superior functional outcome in those with a colon pouch and pouch–anal anastomosis.

How does it work?

In simplistic terms, it is attractive to conceptualize the colon pouch as a neorectum, taking over the complex reservoir function previously performed by the natural rectum. However, physiological assessment suggests that the situation is more complex. Anal canal and MSP are no different before and after operation[69]; nor are they different between patients having a colon pouch or a straight coloanal anastomosis[67,68,70]. A comparison of high anterior resection and low anterior resection with a colon pouch showed no differences in MRP or MSP[71]. While these results suggest that pouch construction is unlikely to result in *impaired* sphincteric function, they also suggest that the improved functional outcome associated with a colon pouch is unlikely to be a consequence of *improved* sphincter function. Interestingly, physiological data from the earliest reports suggested that there was a greater threshold volume and maximum tolerable volume within the colon pouch[64]. These findings have been verified by others[67–69], although work from this unit, within the context of a prospective randomized trial, failed to confirm such findings[70]. Maximum tolerable volume appeared inversely proportional to bowel frequency in several studies, suggesting that the colon pouch may function as a reservoir which both increases capacitance and, possibly, improves compliance, thereby mimicking the rectal property of receptive relaxation. This allows the pouch to distend with faecal contents before intraluminal pressure increases and the desire to defaecate intervenes.

RAIR recovers in 30–100 per cent of patients with a colon pouch[64,67–69], suggesting a re-establishment of the neurogenic pathways necessary for this reflex and, importantly, a coordination of neurogenic and myogenic activity between the pouch and the anal canal. Ambulatory manometry has been used to study 12 patients with a colon pouch (four with minor soiling); in those with a continence disorder there was a much lower pressure gradient between the pouch and the anal canal. However, for the remaining patients, anorectal pressure gradients were similar to those of a group of controls[72]. More interestingly, however, was the demonstration of sampling episodes between flatus and faeces. The importance of this study is its demonstration of the re-establishment of coordinated sensorimotor activity between the colon pouch and the anal canal. In a comparison of functional outcome in patients having high anterior resection (i.e. with a remnant rectum) and those having ULAR with a colon pouch, Ramirez *et al.*[71] found no statistical differences between the two groups in terms of manometric data and functional outcome. They therefore concluded that the colon pouch was behaving as a neorectum.

The possibility of a humorally-mediated mechanism of pouch function has been investigated by measuring levels of peptide YY and enteroglucagon in patients having colon pouches. Peptide YY is a potent inhibitor of intestinal transit and stimulates absorption[73–75]; it is secreted largely in the distal colon and rectum[76]. Enteroglucagon appears to be a trophic stimulant to the gut mucosa[77]. In a randomized trial of patients with a colon pouch *versus* straight anastomosis, Hallböök *et al.*[78] failed to detect any difference in plasma concentration of either peptide at any time period after surgery between the two groups. They concluded that neither of these humoral agents was a factor in determining pouch function. Based on the data presently available, one can only surmise that pouch function is a complex physiological process involving the integration of sensory, motor (and possibly humoral) responses between the pouch and the anal canal.

How big should the pouch be?

Pouch size remains a source of some debate. Initial reports described pouches of 8 cm[65,66], 9 cm[68] and 10 cm[67], with Lazorthes *et al.*[64] using pouch sizes of 6 cm and 12 cm. One of the major drawbacks of a colon pouch is evacuation difficulty. In one early series from Paris, 25 per cent of 162 patients had to use suppositories or enemas to achieve evacuation and avoid impaction with overflow[66]. This assessment was at 1 year following closure of colostomy and initiation of pouch function. Similar problems have been described by other workers: 48 per cent of patients with a 9-cm pouch by Pelissier *et al.*[79], 37 per cent of patients with a 9-cm pouch by Mortensen *et al.*[69] and three of nine patients with a 10-cm pouch by Nicholls *et al.*[67].

Banerjee and Parc have attempted to solve the problem of ascertaining optimum pouch size by using a mathematical model[80]. This was based on the assumption that pouch volume is a function of the length of colon used and colon diameter. The conclusion was an optimum pouch size of 8–10 cm. Unfortunately, this simplistic approach is fundamentally flawed as it fails to account for the physiological characteristics of the neorectum, in particular, motility. In a clinical study to determine optimum size, 40 patients were randomized to have either a 5-cm or 10-cm pouch after ULAR[81]. Although some physiological variables (threshold volume, maximum tolerated volume and compliance) were less in the 5-cm group, the functional outcome was essentially identical between the two groups. Both groups underwent a balloon expulsion test to assess evacuatory function. This was performed by inserting a balloon into the pouch and filling it with 500 ml saline; the patient was then instructed to attempt to expel the balloon in the sitting position and the volume expelled was measured. The expelled volume in the 5-cm pouch groups was significantly greater than that in the 10-cm group a mean(s.d.) of 430(32) *versus* 279(65) ml ($P<0{\cdot}001$, Student's t test). The authors concluded that, in terms of functional outcome, a 5-cm pouch was as good as a 10-cm pouch, but without the evacuatory problems of the larger construction[81]. This finding is of interest as it confirms that pouch function is not a simple mathematical derivative of reservoir capacity. It also gives credence to the contention that pouch function may in some way be related to altered motility, possibly to reversed peristaltic movements in the J pouch reducing transit time[70]. It is likely that the future trend will be to a small pouch size, probably 5–7 cm in length. A pouch size of 8–10 cm is too long if evacuatory problems are to be avoided.

Which part of the colon should be used?

Both sigmoid[65,66] and descending[70,82] colon have been used to construct a pouch. The choice of which to use has not been the focus of any particular study and so it is difficult to be objective. Oncological and operative factors may largely determine which part of the colon is most suitable. In a Western society with an ageing population in whom diverticular disease of the sigmoid may be quite prominent, it seems unwise to choose this part of the colon from which to construct a pouch. Similarly, in a relatively young person with a healthy colon, it may appear inappropriate to excise more colonic tissue than is necessary (once oncological principles have been satisfied). If there is concern about adequate lymphatic clearance when using the sigmoid, it is reassuring to note that after a comprehensive assessment of the lymphatic spread of rectal cancer Hida *et al.*[83] found node positivity to be less than 1 per cent at this level. These authors felt justified in using the sigmoid colon for pouch construction. However, it is the present authors' belief that routine excision of the sigmoid colon is preferable, using the descending colon after full splenic mobilization for pouch construction; these are key factors in optimizing functional outcome[84].

Does pouch construction affect anastomotic leak rate?

The concept of a colonic end-to-side anastomosis in the pelvis is not new. As far back as 1950 Baker[85] reported, in a retrospective study, a leak rate of 23 per cent for conventional end-to-end colorectal anastomosis and only 4 per cent with a side-to-end anastomosis. It is of interest to note that in the colon pouch series from Berger *et al.*[66] pelvic sepsis/anastomotic leakage occurred in only five patients (3 per cent). Similarly, in another small series of 23 patients with a colon pouch there were no documented leaks[86]. This compares favourably with leak rates observed following stapled low coloanal anastomoses which range from 5 to 15 per cent[87–91].

Successful bowel anastomoses are those without tension and with a good blood supply. It is not possible to investigate formally the effect of tension within an anastomosis in the clinical setting, but it is possible to investigate blood flow. One study investigated colonic blood flow using laser Doppler flowmetry within a randomized control trial of pouch *versus* straight anastomosis[92]. Measurements of blood flow were made at the bowel end (i.e. after mobilization and transection) and at a point 8 cm proximal to the end (i.e. the site of proposed colon pouch–anal anastomosis). Blood flow at the end of the bowel was significantly lower after mobilization of the colon, whereas at the bowel wall 8 cm proximally there was no significant change. It was concluded that the blood supply to a colon pouch–anal anastomosis was better than that to a straight colorectal or coloanal anastomosis. This may, in part, explain the apparently lower anastomotic leak rates noted in colon pouch–anal anastomoses.

Functional outcome

From the earliest reports it was apparent that the functional outcome using a colon pouch–anal anastomosis was superior to that of a straight coloanal anastomosis; this was evident well within the first year after operation[64–66]. Although coloanal anastomoses may be associated with a satisfactory outcome in some patients[93], for others poor sphincteric function coupled with urgency and frequency of defaecation prove crippling. Not surprisingly, the functional improvement following colon pouch–anal anastomosis after ULAR described in early reports was enthusiastically received. Lazorthes *et al.*[64] found that after 1 year, 86 per cent of patients with a colon pouch had a bowel frequency of less than 3 stools per day, compared with only 33 per cent of patients with a straight coloanal anastomosis. The results were even more dramatic in the series reported by Parc *et al.*[65] who described a mean of 1-6 bowel movements per day after 1 month and 1·1 per day after 3 months in a group of 31 patients with a colon pouch. The only potential disadvantage of the pouch was faecal retention secondary to poor evacuation. This was observed in 25 per cent of patients in one of the early series; these patients required suppositories on alternate days[66]. The functional outcome of colon pouch–anal anastomosis in these early and subsequent series are presented in *Table 1*. What is striking is that all studies confirm a reduction in bowel frequency and a reduced incidence of urgency from the use of a colon pouch. More recently, three prospective randomized controlled trials have been performed to compare directly physiological and functional outcome following ULAR in patients with or without a colon pouch (*Table 2*). Again the colon pouch emerges as the superior option. It improves functional outcome, with reduced bowel frequency, reduced need for antidiarrhoeal medication and reduced incidence of urgency.

Conclusion

It is now beyond doubt after ULAR that a colon pouch proximal to the anastomosis produces superior functional results compared with those of a straight coloanal anastomosis. Improvement is apparent from the early postoperative period when function may be at its most critical. This is especially important in the elderly who often have impaired sphincter function, which may be easily

overwhelmed by the urgency and frequency associated with a coloanal anastomosis. For those with limited life expectancy it is also desirable to achieve optimum results as quickly as possible. At a time when the indications for APR appear to be reduced or even non-existent for cancer of the lower third of the rectum[99,100], the superiority of the colon pouch over straight coloanal anastomosis should make pouch construction more widespread in this situation.

Review

Quality of life after treatment for rectal cancer

J. CAMILLERI-BRENNAN and R. J. C. STEELE

University Department of Surgery, Ninewells Hospital and Medical School, Dundee DD1 9SY, UK
Correspondence to: Mr J. Camilleri-Brennan

Background The studies on patient-reported symptoms and quality of life following the treatment of rectal cancer were evaluated; guidelines for future quality of life studies in this field are proposed.
Methods Relevant papers in the English language were identified via Medline from January 1970 to November 1997, supplemented by a manual search for similar articles.
Results Patients suffer various short- and long-term complications after treatment of rectal cancer, although the reported prevalence of such problems varies from study to study. Recent prospective studies have shown that, despite these problems, global quality of life scores as measured by generic questionnaires improve after surgery.
Conclusion The methodological shortcomings of previous work must be rectified if quality of life studies are to have relevance in patient management.

Rectal cancer is a tumour of major importance, representing 40 per cent of colorectal cancers. It is a disease which mainly affects the elderly, and has its highest incidence in Western Europe and North America. The reported incidence in 1991 for England and Wales was 20 per 100 000, with a mortality rate of 11·1 per 100 000 for that same year[1,2].

Surgery is the definitive form of treatment for rectal cancer; by resecting the tumour the surgeon not only aims to cure the patient but to relieve distressing symptoms[3]. Unfortunately, patients must suffer adverse consequences from such surgery. The operative dissection of the rectum may damage the pelvic autonomic nerves, disturbing bladder and sexual function[4,5]. The construction of a permanent colostomy following an abdominoperineal resection may be associated with clinically significant psychological problems[6]. With advances in knowledge of tumour biology and improvements in surgical instruments and techniques, survival and tumour recurrence rates are similar after anterior resection and abdominoperineal resection[5,7], resulting in an increasing number of restorative procedures being performed. Although avoidance of a permanent stoma is generally regarded as a favourable outcome measure, patients undergoing sphincter-saving surgery may develop a number of unpleasant symptoms, typically faecal soiling and urgency, especially with low anastomoses[8–19]. The provision of a colonic pouch reservoir may reduce such problems, but difficulties with evacuation of the neorectum have been described[20].

It is evident that the consequences of rectal surgery have an important bearing on a patient's quality of life. Although differences in definition exist[21,22], 'quality of life' may be regarded as representing an individual's ability to carry out daily activities, as well as satisfaction with personal performance and with the balance between disease control and adverse effects of treatment[22]. Quality of life is assessed by using specifically designed questionnaires which test the various components of physical, social and psychological well-being[21–23].

The aim of this review is to evaluate the studies of one or more components of quality of life and to outline proposals for future quality of life studies in rectal cancer surgery. Studies on the effect of radiotherapy and chemotherapy for advanced disease on quality of life are also discussed.

Study design

A total of 54 papers published in the English language on aspects of quality of life in rectal cancer surgery was analysed. Forty were cross-sectional or retrospective studies and 14 were prospective studies. In only three studies was global quality of life formally measured using a well researched questionnaire[24–26]. The others investigated only isolated symptoms using, in most cases, unresearched and unvalidated questionnaires. Sample sizes in these studies varied from five to 265, with the majority involving groups of less than 25 patients; follow-up was from 1 month to 30 years after surgery. Some reports did not distinguish between short-term and long-term complications.

One study assessed quality of life in patients with colorectal cancer who were having radiotherapy[27]; another six assessed quality of life during chemotherapy and radiotherapy[28–33]. Well validated questionnaires were used in only three of these studies.

Statistical analysis of results was used in most reports; the commonest test measuring significance was χ^2 analysis.

Social well-being

Social problems encountered by patients after rectal cancer surgery were described in eight cross-sectional studies. Devlin *et al.*[34] reported in 1971 that 51 per cent of patients over 65 years old who had a colostomy felt socially isolated, in contrast to 19 per cent of younger patients with a stoma. Women felt more socially isolated than men. Wirsching *et al.*[35] in 1975 examined a group of 214 patients who had a permanent colostomy and a group of 110 who had restorative surgery. There was significantly

Paper accepted 23 February 1998

reduced social contact in the colostomy group. Similarly, MacDonald and Anderson[36] in 1985 noted that those with a colostomy tended to participate less in social activities than those without a stoma; their interests in outdoor pursuits were significantly less. A statistically significant difference was also noted by Williams and Johnston[8] who compared the leisure pursuits of patients with a colostomy (50 per cent decrease) and those without (18 per cent decrease). Despite all of this, Frigell *et al.*[10] in 1990 were unable to detect any difference in the rate of decreased social activities when they compared patients with an anterior resection with those with an abdominoperineal resection (19 *versus* 17 per cent). Indeed, 74 per cent of those with an anterior resection avoided public societies compared with 59 per cent of those with abdominoperineal resection.

In 1984 MacDonald and Anderson[37] found a worsening partner-relationship in 29 per cent of patients with a colostomy compared with 14 per cent of those who had a sphincter-saving resection. This result was statistically significant. On the other hand, La Monica *et al.*[38] in 1985 did not find any such difference. In a study by von Smitten *et al.*[39] in 1986, only one patient reported severe impairment of his social life due to a colostomy; 13 of 54 patients reported only minor impairment.

Social life may deteriorate after surgery for rectal cancer, although results are contradictory. A colostomy may bring a fear of being a nuisance to other people, mainly because of odour, and there may be embarrassment about the presence of a stoma[10,35,37,39]. However, similar problems beset those who are incontinent of flatus and/or faeces following a restorative rectal resection[10].

Psychological well-being

Psychological aspects of quality of life have been researched in four cross-sectional studies. Devlin *et al.* in 1971[34] found that 23 per cent of 83 patients suffered from a severe form of psychological disturbance after abdominoperineal resection, compared with one of 37 patients who had a sphincter-saving operation. These data were not tested statistically. Williams and Johnston[8] in 1983 reported a 32 per cent prevalence of depression following an abdominoperineal resection, compared with a 10 per cent prevalence after anterior resection. These researchers used the 'Leeds Self-Assessment of Depression and Anxiety Scales' and their results were statistically significant. Sixty-six per cent of their patients were distressed after abdominoperineal resection because of an alteration in body image caused by the colostomy; only 5 per cent expressed concern about physical appearance after a sphincter-saving procedure.

In 1975 Wirsching *et al.*[35] understood that a colostomy was associated with a significant degree of depression, hopelessness, loneliness and suicidal thoughts. They used the Heidelberg Colostomy Questionnaire in their study which covered mainly social and psychological function in patients with a stoma. The patients after abdominoperineal resection studied by MacDonald and Anderson[37] in 1984 were found to have a statistically significant higher incidence of low self esteem and feelings of stigma than those who had undergone a sphincter-saving resection. In agreement with the observations made by Williams and Johnston[8], these authors stated that those with a colostomy were more concerned about their appearance than those with an anterior resection. However, the incidence of anxiety in the two operated groups was similar, as was the incidence of depression.

These studies show a high prevalence of psychological problems in patients operated for rectal carcinoma, even though the instruments used in most cases may not be psychometrically reliable. Patients with colostomies tend to suffer most[8,34,35,37,40]. The degree of psychological distress before surgery was not recorded in any of these studies.

Physical well-being

There were 49 studies which dealt with the effect of rectal cancer surgery on physical well-being. Symptoms investigated pertained mainly to sexual, urological and defaecatory functions.

A spectrum of sexual problems may arise in men[8,34,35,38,41–59]. These typically involve erectile and ejaculatory dysfunction (*Table 1*), although other symptoms, such as a loss of desire, diminished sexual activity and anorgasmia, may occur. Sexual problems in women have not been as extensively researched. The problems described are fewer, and are mainly cessation of intercourse, anorgasmia and dyspareunia[34,35,50,60]. Both men and women who have had an abdominoperineal resection or a low anterior resection tend to have a higher prevalence of sexual problems than those with a high anterior resection[34,41–43,50,53]. There is also a high prevalence in the elderly[46,56]; male sexual problems appear generally to increase with age, although not all authors agree on this[48].

Urological difficulty following surgery has also been described[36,46,48,50,51,58,61–64], especially incontinence, retention and dysuria. The relevant studies are summarized in *Table 2*. As with sexual problems, abdominoperineal resection is associated with more urological problems than anterior resection[36,48,50], but results in some studies are not statistically significant.

Sexual and urological symptoms usually occur secondary to damage to the pelvic autonomic nerves and pelvic floor sustained during dissection of the rectum[4,5]. Operative techniques such as total mesorectal excision with autonomic nerve preservation, in which the pelvic nerves are carefully identified during surgery, may result in less sexual and urinary dysfunction[5,58,59,65].

A number of studies have been carried out to assess bowel and sphincter function after surgery for rectal cancer (*Table 3*). The common symptoms are frequency of bowel motion, urgency, and faecal leakage or incontinence[8–15,17–20,66–70]. Some authors also report on the prevalence of diarrhoea, constipation and flatus[8,10,34,36]. Many relevant issues emerge from such work. Bowel function, which may be erratic before surgery because of the tumour, may not improve after operation[18]. According to Williams and Johnston[8], the frequency of bowel motions is usually greater after abdominoperineal resection than after anterior resection, but Frigell *et al.*[10] disagree. Patients with a colostomy tend to have more problems with flatus and foul odour than other patients[8,36], but the prevalence of diarrhoea is similar in both groups[36].

Bowel function after sphincter-saving resection depends on several factors. The level of anastomosis may be relevant. A low colorectal or coloanal anastomosis is associated with a higher frequency of defaecation and a higher prevalence of faecal leakage and incontinence than a high colorectal anastomosis[11,17,49,65], although not all studies agree on this[10,16]. Defaecatory problems may also arise from surgical trauma to the anal sphincter and its innervation[16]. Anorectal physiological assessment shows that the threshold reservoir volume and maximum tolerable volume are significantly lower after a low colorectal or coloanal anastomosis than after a higher anastomosis[17]. The maximum resting pressure and, in some cases, the maximum squeeze pressure, which measure the internal and external anal sphincters respectively, are lowered after operation[11,13,17,71,72]. Any improvement of bowel function in the long term is usually reflected by an improvement in the physiological status of the anoneorectum[13,17,71,72]. In patients who experience poor function, however, the anal sphincter pressures and the rectoanal inhibitory reflex remain abnormal[15,65,71,72]. The construction of a colonic J pouch may improve bowel function in those who undergo a low anterior resection[14,15] as the threshold and maximum tolerable volumes of the neorectum increase[66,67]. However, difficulties in evacuation of the pouch may occur[20], especially with pouches of a larger volume[73], requiring the use of a suppository or an enema. A number of patients may remain plagued with defaecatory problems, and may require revisionary surgery[19].

Formal quality of life studies in rectal cancer surgery

To date there are only three reports in the English language literature which describe formally measured quality of life in all its dimensions after surgery for rectal cancer[24–26]. All three studies used the Nottingham Health Profile, a questionnaire which measures the subjective

psychological, functional and social impact of disease[74]. Its reliability and validity are proven. In addition, one study[24] used a shortened version of the Health Measurement Questionnaire, while another[25] used a selection of questions from the Rotterdam Symptom Checklist, the latter questionnaire being validated for use in patients with cancer[75].

In a retrospective study by Whynes *et al.*[24] in 1994 of over 400 individuals, no difference was found between the scores of 77 patients with a colostomy and those of patients with a restorative surgical procedure for colorectal cancer. However, the same authors in 1997, in a prospective study of 49 patients[25], noted an improvement in some postoperative scores for all colorectal operations compared with preoperative scores. The main area of improvement was in the emotional reactions dimension.

In 1997 Hallbook *et al.*[26] commented on the general quality of life before and a year after restorative rectal cancer surgery; this occurred as part of a prospective randomized trial comparing a straight and a colonic J pouch anastomosis. The scores improved in both groups after operation; there was no difference in scores between the two groups. So global quality of life, measured by the Nottingham Health Profile, was similar, despite the superiority in bowel function in patients with a J pouch which had been demonstrated in an earlier study[69].

Effect of radiotherapy and chemotherapy

Both preoperative and postoperative adjuvant radiotherapy have been shown recently to decrease the incidence of local recurrence of rectal cancer[76]. A beneficial effect on survival has been demonstrated in one recent study using preoperative radiotherapy[77]. However, a number of short-term and long-term complications of treatment are recognized. In the short term, there is a statistically significant increase in the incidence of perineal wound infection after abdominoperineal resection preceded by radiotherapy[78]. In the long term, both preoperative and postoperative radiotherapy are associated with an increased incidence of venous thromboembolism, arterial disease, fractures of the pelvis and femoral neck, intestinal obstruction, colovesical and colovaginal fistula, and urinary tract infection[79,80]. The effect of preoperative radiotherapy on anorectal function is minimal[81,82], but radiotherapy administered after an anterior resection may have a detrimental effect on sphincter function, rectal capacity and clinical outcome[83]. One study assessed quality of life over the duration of pelvic radiotherapy for colorectal cancer[27]. As measured by the Health Quality of Life Index, quality of life appeared to remain at an acceptable level throughout the treatment.

The toxicity of chemotherapy and its impact on quality of life has been examined in patients with advanced metastatic colorectal disease. Six prospective studies were identified[28–33]. Toxic side-effects include anaemia, neutropenia, diarrhoea, nausea, vomiting, anorexia and alopecia. Glimelius *et al.*[28] reported an overall improvement in quality of life scores in 36 per cent of patients with metastatic colorectal cancer receiving chemotherapy. The same authors had previously reported that patients receiving both methotrexate and 5-fluorouracil (5-FU) had a better quality of life than those receiving 5-FU alone[29]. However, Laufmann *et al.*[30] found no difference in quality of life scores between patients having 5-FU and placebo and those having 5-FU and leucovorin. Seymour *et al.*[31] showed that the addition of interferon to 5-FU and leucovorin was associated with a decreased quality of life; this study used the Rotterdam Symptom Checklist and the Hospital Anxiety and Depression Score.

Two studies have combined quality of life and survival into a single measure in order to compare treatment regimens. In one, hepatic artery infusion of floxuridine for colorectal liver metastases was found to prolong both overall and normal-quality survival, compared with conventional palliative therapy[32]. The Rotterdam Symptom Checklist and the Hospital Anxiety and Depression Score were used in this study. In the other study, Gelber *et al.*[33] combined quality and quantity of life using a Quality-adjusted Time without Symptoms and Toxicity analysis. The time with toxic side-effects of chemotherapy and radiotherapy was subtracted from the overall survival time. Although there was more toxicity associated with combined chemotherapy and radiotherapy than with radiotherapy alone in patients with rectal cancer and lymph node metastases, the time spent free of any symptoms or side-effects was greater in the combination group than in the radiotherapy group. The social and psychological dimensions of quality of life were not assessed and so it is not known which treatment regimen is more beneficial to well-being.

Discussion

After potentially curative surgery for rectal cancer, patients may suffer from a range of problems affecting the physical, social and psychological aspects of their life. Physical problems are related mainly to sexual[8,34,35,38,41–60], urinary[36,46,48,50,51,58,61–64] and bowel[8–20,66–70] function. Men suffer from impotence and ejaculatory difficulties, among others, while women suffer mainly from dyspareunia. Urinary problems include incontinence, retention and dysuria. The prevalence of these symptoms is on the whole greater with an abdominoperineal resection than with an anterior resection, and such symptoms generally increase with age. Most studies report a higher incidence of faecal incontinence and frequency of defaecation after a low anterior resection than after a higher anastomosis. Defaecatory problems have, in general, been improved by the provision of a colonic J pouch. Social[8,10,34–39] and psychological[8,34,35,37] problems are present after both sphincter-saving and sphincter-sacrificing surgery, although such problems may be more prevalent with the latter.

Although such work clearly demonstrates complications, it fails to show how the overall quality of a patient's life is affected as a result of rectal cancer and its

*Values in parentheses are percentages; †values are median (range) or ‡mean(s.d.). §Level of anastomosis from anal verge. APR, abdominoperineal resection; SSR, sphincter-saving resection; AR, anterior resection; LAR, low anterior resection; CPA, colopouch–anal anastomosis; CA, coloanal anastomosis treatment. Studies that assessed quality of life have so far shown an overall improvement after operation, irrespective of the operation performed[24-26]. Such results are unexpected because patients with a stoma were perceived to have poorer quality of life than other patients with restorative rectal surgery[8,34-37,84]. Adjuvant radiotherapy is associated with a number of complications, but its effect on quality of life must be assessed in more depth[27]. Some chemotherapy regimens for advanced metastatic colorectal cancer are better than others in terms of quality of life, although the methods of measurement of quality of life differ from study to study[28-33].

More work is needed on quality of life and rectal cancer[84]. Prospective studies of sufficiently large numbers of patients should be carried out to assess quality of life before and after operation[21-23,85,86] and, since quality of life changes over time, measurements should be made at various intervals after surgery[21-23,85-87]. Assessment should also be made during adjuvant treatment to evaluate the impact of such treatment on quality of life[88,89]. Current prospective chemotherapeutic trials in rectal cancer are already using quality of life as a serious study end point.

It is well known that a large amount of information on quality of life may be obtained by detailed interview[21-23]. However, this approach is not practical for routine use where a questionnaire that is short and in simple language is needed to allow easy completion. This enhances patient compliance despite repeated administration[21-23,87]. Despite its brevity, such a questionnaire should still ideally cover all aspects of quality of life. It should also have certain properties to make it psychometrically sound, unlike many of the questionnaires that have been used in the studies described in this review. The instrument must be of proven validity, that is it must measure the intended variable and not another. It must be reliable, measuring the variables accurately, and also sensitive, measuring any changes present[21-23,87].

Generic questionnaires, such as the Nottingham Health Profile, are useful and allow the researcher to compare quality of life across whole patient populations[67]. However, they may not be sensitive enough to measure changes in quality of life which may be brought about by different types of surgery or adjuvant treatment. This may have been the case where the Nottingham Health Profile was used in some recent studies[24-26]; in these no treatment difference was found between either an abdominoperineal resection and a restorative colorectal resection, or between a low anterior resection with colopouch anal anastomosis and a low anterior resection with a straight coloanal anastomosis. On the other hand, differences in global quality of life associated with different operations may truly not exist, the benefit of surgery resulting solely from the removal of the tumour, irrespective of the surgical technique used. Questionnaires which have been designed for use in patients with cancer, such as the Rotterdam Symptom Checklist[75] and the European Organisation for Research and Treatment of Cancer (EORTC) QLQ-C30 core questionnaire[90], may be more suitable. In addition, further questionnaires specific to colorectal cancer are necessary. For example, the EORTC group has recently developed a colorectal cancer questionnaire or module (QLQ-CR38), which has been validated in the Netherlands and is being tested in a number of international phase III trials[91].

Doctors have been noted in various studies to be poor assessors of their patients' quality of life[92-94]. It is therefore important that valid measures of quality of life should be constructed, involving the patients themselves, thereby eliminating observer bias and interobserver variation[92].

Conclusion

Quality of life studies in oncology are of increasing importance. Their main aim is to determine the impact of cancer and its treatment on patients' well-being. In addition to traditional endpoints, such as survival and disease recurrence, quality of life assessment is necessary to provide a proper, comprehensive understanding of the outcome of surgery and other forms of treatment. Quality of life studies may also be used to evaluate the quality of care which patients receive, potentially allowing management to be improved and services to be designed to alleviate distress.

Background For most solid tumours, surgery remains the most effective primary treatment. Despite apparently curative resection, significant numbers of patients develop secondary disease due to growth of undetected micrometastases. The ability of a tumour to metastasize is related to the degree of angiogenesis it induces. In addition, micrometastases rely on new vessel formation to provide the nutrients necessary for growth. A better understanding of how tumours acquire their blood supply may lead to more effective adjuvant therapies and improve survival following surgery.

Methods A systematic review of the literature on angiogenesis between 1971 and 1997 was performed using the Medline database to ascertain current thinking on angiogenesis and its relevance in oncological surgery.

Results Angiogenesis is a physiological process subject to autocrine and paracrine regulation which has the potential to become abnormal and play a part in a number of pathological states, including cancer. Increased angiogenic stimuli in the perioperative period, associated with concomitant reduction in tumour-derived antiangiogenic factors following resection of a primary tumour, result in a permissive environment which allows micrometastases to grow.

Conclusion Recognition of the role of angiogenesis in metastatic tumour growth represents a significant development in our understanding of tumour biology. The development of antiangiogenic agents offers new promise in the treatment of malignancy. Such agents may prevent or control the development and growth of primary and metastatic tumours.

Angiogenesis is a process through which new blood vessels develop from pre-existing vessels such as capillaries and postcapillary venules[1,2]. It is tightly regulated by a large number of proangiogenic and antiangiogenic factors. In physiological circumstances, angiogenesis is fully controlled by an equilibrium between these factors such that little blood vessel growth occurs in the healthy adult. Accelerated angiogenesis is a normal physiological response to wound healing, inflammation, menstruation and embryonic development, but a pathological feature of conditions such as diabetic retinopathy, rheumatoid arthritis and solid tumours.

The pivotal role of angiogenesis in primary tumour growth and metastasis has been recognized for many years, although the mechanisms which control it are incompletely understood[3]. Growth of a tumour beyond 2–3 mm^3 requires development of a microvessel network to facilitate delivery of nutrients and oxygen, and removal of catabolites. Density of microvasculature has been used as an indicator of biological aggressiveness and metastatic potential in many primary tumours[4], as neovascularization facilitates metastasis[1,5] by providing access to the circulation[6,7]. The degree of angiogenesis in primary breast[8], prostate[4] and colorectal[9] carcinoma correlates with lymph node metastasis. The predictive value of microvessel density in the primary tumour remains controversial. Microvessel density has been shown to be an independent prognostic indicator in non-small cell lung cancer[10], certain instances of node-negative breast cancer[11,12] and several other carcinomas[13]. However, conflicting reports exist, particularly in relation to its prognostic value in breast cancer[14,15]. These conflicting findings may be attributable, in part, to the heterogeneity of microvessel density within individual tumours, as well as to interlaboratory and interobserver variability in microvessel counting[12].

Our understanding of mechanisms regulating angiogenesis in metastatic disease is increasing[16]. Acquisition of a blood supply by micrometastases at the site of implantation is crucial to tumour growth. Neovascularization is promoted by a number of proangiogenic factors of tumour and stromal origin. The clinical impression that resection of a primary tumour heralds a phase of increased metastatic growth is of particular interest, but until recently no explanation of this phenomenon existed. Recent studies have shown that the intact primary tumour can regulate growth of associated metastases, either directly or indirectly, through the production of certain antiangiogenic factors, notably angiostatin[17]. Surgical excision of a primary tumour removes the source of the inhibitory angiostatin and other factors, allowing angiogenesis and subsequent growth of previously dormant micrometastases[18]. Tumour recurrence many years after apparently successful treatment of a primary lesion is partly the result of increased angiogenesis[19,20]. Long-term suppression of angiogenesis may become a therapeutic option for induction of long-term remission by maintaining micrometastases in a state of dormancy, a dynamic equilibrium during which there is no net tumour growth[20]. The proliferating capillary endothelial cell offers a unique target for antiangiogenic therapy[21] as antiangiogenic strategies may reduce both the recurrence rate and the metastatic potential of solid tumours[22].

Paper accepted 9 March 1998

Stages of neovascularization

Newly formed capillaries are composed of two cell types, endothelial cells and pericytes. These two cells have the capacity to produce entire capillary networks. Following the transduction of signals which promote differentiation *in vivo*, angiogenesis progresses in four stages: activation of endothelial cells, proliferation, migration and lumen formation[23].

Cytokine release is provoked by factors endogenous and exogenous to tumour cells, including local environmental factors such as hypoxia. Quiescent endothelial cells are activated by the release of cytokines from host and tumour cells (stage 1). Committed cells proliferate (stage 2), then migrate along a fibrin skeleton towards the source of the angiogenic stimulus to form cords of aligned cells (stage 3). Finally, the vascular sprout forms a lumen and the cells exit the cell cycle to a resting phase. Development of a patent lumen (stage 4) occurs through coalescence of intracellular vacuoles and is facilitated by cell-to-cell adhesive contact[1].

Degradation of the extracellular matrix is an essential component of new vessel invasion. This is facilitated by alteration of the proteolytic balance. Proteolytic degradation of the extracellular matrix and fibrinolysis are two functions of pericytes[24], although pericytes are also thought to contribute by production of growth factors and growth inhibitors. Cell adhesion receptors promote vascular cell migration through interaction with adhesion proteins of the extracellular matrix, such as collagen and fibronectin. The extracellular matrix also serves as a reservoir for growth factors, particularly acidic fibroblast growth factor and basic fibroblast growth factor (bFGF)[25–27].

The capillary sprouts in tumours are 'leaky' as proliferating capillaries have incomplete basement membranes. In addition, vascular endothelial growth factor (VEGF; previously known as vascular permeability factor) increases permeability through the development of a series of interconnected cytoplasmic vesicles and vacuoles (known as vesical-vacuolar organelles) that maintain contact with both the luminal and abluminal surface[28,29]. In normal tissues this may play a regulatory role in controlling baseline microvascular permeability[30], and in tumour microvasculature this feature has been linked to malignant exudates and ascites[31,32].

Regulation of angiogenesis

The degree of angiogenesis in a tumour is the result of complex interactions between tumour cells, capillary endothelial cells, pericytes and recruited immune cells with products of these cells acting in both an autocrine and paracrine fashion[33]. It is normally subject to tight physiological control through a balance of proangiogenic and antiangiogenic factors. These factors allow a phase of rapid proliferation to facilitate wound healing but maintain quiescence in the mature microvasculature[5]. Increased production of positive angiogenic factors is 'necessary but not sufficient'[34] for induction of the angiogenic phenotype; negative regulators must also be decreased[18,35,36]. Imbalance between angiogenic promoters and inhibitors produces the intense angiogenesis which is characteristic of many pathological processes, including diabetic retinopathy[37–39], rheumatoid arthritis[40], endometriosis[41] and malignant tumours[29,42].

Factors influencing angiogenesis are derived both from tumour cells and infiltrating cells, such as macrophages and fibroblasts[7]. Through their secretory products, activated macrophages can influence each phase of the angiogenic process[43–45]. The process of macrophage activation is mediated in part by hypoxia[46]. The large number of macrophages present in a variety of angiogenesis-associated pathological states is indicative of their influence. It is known, for example, that numerous macrophages are present in the first phase of tumour growth. Macrophage density is directly proportional to rate of tumour growth in breast carcinoma[47]. Furthermore, tumour-associated macrophages cause marked augmentation of tumour neovascularization[40] and correlate directly with prognosis in this disease[48]. Other immune cells are also significant, as neutrophilia is associated with a poorer prognosis in breast cancer[49].

Proangiogenic factors (*Table 1*)

Vascular endothelial growth factor

VEGF is the most potent directly acting angiogenic protein known[50]. It is a diffusible endothelial cell-specific

Table 1 Proangiogenic substances

Substance	Reference	Year
Vascular endothelial growth factor	Marme[50]	1996
Basic fibroblast growth factor (FGF-2)	Rifkin and Moscatelli[74]	1989
Acidic fibroblast growth factor (FGF-1)	Jouanneau *et al.*[177]	1995
Platelet-derived endothelial cell growth factor	Takahashi *et al.*[7]	1996
Platelet activating factor	Camussi *et al.*[178]	1995
Transforming growth factor $\beta 1$	Pepper *et al.*[102]	1993
Transforming growth factor α	Gleave *et al.*[179]	1993
Insulin-like growth factor	Nicosia *et al.*[180]	1994
Epidermal growth factor	Goldman *et al.*[181]	1993
Interleukin 1	Fan *et al.*[182]	1993
Interleukin 4	Wojta *et al.*[183]	1993
Interleukin 6	Sunderkotter *et al.*[43]	1994
Interleukin 8	Smith *et al.*[184]	1994
Interleukin 15	Angiolillo *et al.*[185]	1997
Angiogenin	Moenner *et al.*[186]	1994

Fibronectin	Bitterman *et al.*[26]	1983
Fibrin	Tsopanoglau *et al.*[187]	1993
Tumour necrosis factor α (*in vivo*)	Frater-Schroder *et al.*[111]	1987
Endotoxin (lipopolysaccharide)	Mattsby-Baltzer *et al.*[112]	1994
Matrix metalloproteinases	Cornelius *et al.*[188]	1995
Scatter factor (hepatocyte growth factor)	Rosen *et al.*[189]	1993
Hyaluron fragments	Cockerill *et al.*[23]	1995
Granulocyte–macrophage colony stimulating factor	Bikfalvi and Han[190]	1994
Platelet activating factor	Bussolino *et al.*[191]	1995
Proliferin	Jackson *et al.*[192]	1994
Substance P	Fan *et al.*[182]	1993
Lactate	Magee *et al.*[193]	1994
Prostaglandin E_1, E_2	Ben-Av *et al.*[194]	1995
Urokinase plasminogen activator	Hildenbrand *et al.*[195]	1995
Tenascin	Canfield and Schor[196]	1995
Nitric oxide	Ziche *et al.*[197]	1994
Erucamide	Mitchell *et al.*[198]	1996

mitogen and angiogenic factor, which also increases vascular permeability[51,52]. It binds to two endothelial cell tyrosine kinase receptors, the fms-like tyrosine kinase (flt) and the kinase domain receptor (KDR)[53,54].

Tumour-derived VEGF plays an important role in the paracrine stimulation of angiogenesis but it also appears to have an autocrine stimulatory effect on tumour cells[55], particularly in response to hypoxia[56]. Hypoxia stimulates angiogenesis in a number of sites, including endothelial cells, retinal pericytes[57], myocardium[58] and solid tumours[59]. VEGF activity is potentiated by oxygen deprivation[60–62], mediated in part by adenosine[57,63] through upregulation of the VEGF endothelial cell receptor KDR[64]. Wild-type *p53*, a tumour suppressor gene, inhibits proliferation of both normal and transformed cells[65,66], and also regulates VEGF production. Mutations in this gene abolish such control. There appear to be two regulatory VEGF pathways: an oncogenic one (v-*src*) that enhances VEGF production and a tumour suppressor (*p53*) signal that suppresses VEGF[50]. Mutations of the *ras* oncogene cause VEGF upregulation in a colon cancer model with resulting increased angiogenesis[67]. H-*ras* oncogene mutation also activates angiogenesis through upregulation of VEGF and matrix metalloproteinase (MMP) bioactivity, while downregulating activity of tissue inhibitors of MMP[68].

Tumour cell lines which express minimal constitutive and hypoxia-inducible VEGF (e.g. human melanoma SK-MEL-2 cells) produce small, poorly vascularized tumours. Overexpression of VEGF results in dramatically increased angiogenesis and subsequent tumour expansion[69]. Interruption of the VEGF receptor paracrine pathway in glioma tumours inhibits angiogenesis, leading to reduced numbers of new vessels, a higher degree of necrosis and a reduction in size of glioma tumours[70]. Expression of VEGF and its receptor KDR is higher in metastatic than in non-metastatic colonic neoplasms, and correlates directly with the extent of neovascularization and degree of proliferation[9]. There is a direct correlation between serum VEGF concentration and breast cancer stage[71].

Soluble recombinant flt receptor binds to free VEGF and inhibits its mitogenic affinity for endothelial cells[72]. Anti-VEGF antibodies have been used as a new therapeutic modality for the prevention of retinal ischaemia-induced neovascularization of the iris, confirming that the *in vitro* effects of VEGF inhibition are reproducible *in vivo*[73].

Basic fibroblast growth factor

This is a 16-kDa protein which is one of a family of fibroblast growth factors[74]. Capillary endothelial cells themselves produce and release bFGF which acts in an autocrine fashion independently, and synergistically with VEGF[75], as an endothelial cell mitogen[76]. It binds intensely to the extracellular matrix, but is normally confined to its cell of origin as it lacks the signal peptide thought to be necessary for secretion[50]. During the malignant evolution of fibrosarcoma, neovascularization is associated with a switch to the ability to export bFGF from cells[77]. It also stimulates endothelial and vascular smooth muscle cell motility[78,79] especially after arterial trauma[80]. Heparin released by recruited mast cells amplifies its effect[5]. Its systemic administration results in an increased rate of tumour growth and increased vascularity[81]. Binding by bFGF is inhibited by suramin, an antiparasitic agent[82]. It has been shown that blockade of bFGF receptors results in suppression of solid tumour growth[83].

Acidic fibroblast growth factor

This is a heparin binding site-specific endothelial cell mitogen[84,85] which promotes angiogenesis and wound healing[86,87]. It is expressed constitutively in normal as well as in tumour cells, but appears to be inhibited by an angiogenesis suppressor gene which is downregulated during tumorigenesis[34]. Like bFGF, it is found in many normal cells but exported only in tumour cells.

Platelet-derived endothelial cell growth factor

This proangiogenic cytokine is found in platelets[88] and released during the blood clotting cascade, as well as being produced by vascular smooth muscle cells[89]. It is an endothelial cell mitogen but is not a classical growth factor, because direct contact with a cell-surface receptor is not required for its mitogenic capability[90]. It promotes endothelial cell migration[91] and may facilitate endothelial differentiation[92]. Platelet-derived endothelial cell growth factor (PD-ECGF) expression is known to be modulated by the tumour microenvironment[93]. It is homologous to thymidine phosphorylase[94], an enzyme which catalyses the reversible breakdown of thymidine to thymine and deoxyribose-1-phosphate. This enzymatic activity may contribute to its angiogenic activity, as products of deoxyribose-1-phosphate are known to be angiogenic, although the mechanism through which PD-ECGF exerts is angiogenic effect is not yet fully understood[95,96].

Transforming growth factor β

Transforming growth factor (TGF) β, which is produced by macrophages and activated platelets, exists in three human isoforms, $\beta 1$, $\beta 2$ and $\beta 3$. All act as chemotactic agents for macrophages and are indirectly angiogenic *in vivo*[97–100], although TGF $\beta 1$ appears most potent in this regard[100]. TGF $\beta 1$ facilitates wound healing through accelerated collagen deposition and maturation[101]. It induces matrix production and alters integrin production to facilitate neovascularization. It acts in a dose-dependent manner, with low concentrations exhibiting stimulatory and high concentrations inhibitory effects[102]. Its absence results in poor vascular integrity and reduced remodelling[103]. TGF $\beta 3$ appears to have a greater role in matrix remodelling, with a resultant decrease in scar formation[100].

Epithelial growth factor

Epidermal growth factor (EGF) is a mitogenic growth factor. EGF receptors belong to a group of proto-oncogenes, including c-*erbB2*, which are overexpressed in a number of human tumours[104]. EGF is secreted by tumour-associated macrophages in patients with carcinoma of the breast[105].

Integrins

Blood vessels involved in angiogenesis express adhesion proteins, known as integrins, including von Willebrand factor, fibronectin, fibrin and vascular integrin $\alpha v_1 \beta_3$ and $\alpha v_1 \beta_5$. They facilitate cell–cell and cell–matrix interactions[106], thereby playing a crucial role in endothelial cell chemotaxis. Adhesion proteins may be selectively inhibited by monoclonal antibodies with the resulting decrease in angiogenesis inducing apoptosis of endothelial cells[34]. Vascular integrin $\alpha v_1\beta_3$ is selectively expressed on growing vessels, where it suppresses p53 activity while increasing the *bcl2*:*bax* ratio with a net proangiogenic and antiapoptotic effect[107]. Its inhibition by monoclonal antibodies in a melanoma model results in reduced angiogenesis, suggesting that the new tumour vasculature grows in a self-perpetuating manner[108].

Tumour necrosis factor α

Tumour necrosis factor (TNF) α is a macrophage-derived angiogenic factor which is considered to be the principal mediator of tumour cell cytotoxicity and cytostasis[109]. It has a broad spectrum of biological activities including both stimulatory and inhibitory effects on target cells which are dose related[40,110]. It induces granulocyte–macrophage colony stimulating factor production, has procoagulant activity and increases the adherence of human endothelial cells. Its proangiogenic activity was initially postulated to be induced through an inflammatory mechanism secondary to its cytotoxic effects[111]. It is now believed that TNF-α is a potent mediator of angiogenesis at low concentrations, independent of inflammation[110].

Endotoxin

Endotoxin (lipopolysaccharide; LPS) is a ubiquitous molecule derived from the cell wall of most Gram-negative and some Gram-positive bacteria as well as existing in a free form in the environment. It is a proangiogenic molecule because of its ability to elicit production of a wide spectrum of host-effector molecules, such as VEGF, bFGF, TGF-β, TNF, interleukin (IL) 1 and IL-6, by macrophages and other cell populations[112–114]. Recent work from the authors' laboratory shows that LPS introduced at the time of open surgery in a tumour-bearing murine model increases serum VEGF concentration[115].

Antiangiogenic factors (*Table 2*)

Thrombospondin

Thrombospondin is a glycoprotein secreted by many cells, including endothelial and epithelial cells, fibroblasts, smooth muscle cells, monocytes and macrophages[116]. It modulates endothelial cell adhesiveness, motility and proteolytic activity by sequestering angiogenesis inducers[117]. While it is a potent inhibitor of angiogenesis, it is downregulated during tumorigenesis[5,118,119]. In fibroblasts, wild-type p53 inhibits angiogenesis through upregulation of thrombospondin[33], an effect which is abolished by p53 mutations. Paradoxically, thrombospondin enhances the angiogenic effect of LPS and bFGF stimuli in inflammatory states[120]. It is speculated that thrombospondin 1 downregulates VEGF expression through an as yet unknown mechanism[48].

Angiostatin

Angiostatin is a 38-kDa internal fragment of plasminogen[121] which inhibits endothelial cell proliferation, angiogenesis and tumour growth. It blocks the catalytic site of the enzyme that cleaves plasminogen, thereby preventing the matrix remodelling required for angiogenesis[117]. It selectively prevents endothelial cells responding to angiogenic stimuli resulting in dormancy of micrometastases[122]. Systemic administration has been shown to induce regression of primary tumours of breast, colon and prostate in a murine model, providing the first example of dormancy therapy in which tumours undergo regression through blockade of angiogenesis[17].

Table 2 Antiangiogenic substances

Substance	Reference	Year
Thrombospondin	Canfield and Schor[196]	1995

VEGF, vascular endothelial growth factor

Endostatin

Endostatin is a protein fragment of collagen XVIII and was first isolated from a murine haemangioendothelioma cell line[123]. It acts in a similar way to angiostatin, blocking collagenase and impeding matrix remodelling. It specifically inhibits endothelial cell proliferation. Recombinant endostatin inhibits angiogenesis, growth of metastases and growth of primary tumours[123]. Endostatin-treated tumours have a proliferation rate which is the same as that of untreated tumours, but an apoptotic rate which is sevenfold greater, providing a further example of dormancy therapy.

Tumour angiogenesis

Malignant transformation is a cumulative process requiring loss of control of the cell cycle and a shift in the balance of proangiogenic and antiangiogenic factors. Induction of angiogenesis is a local event which is specific to activated hyperplastic cells and which procedes overt tumour formation[124]. For example, angiogenesis is a marker of premalignant transformation in benign breast disease[125,126]. Vascular endothelial cells in malignant breast tumours express tissue factor, a potent procoagulant, whereas vascular endothelial cells in benign tumours do not[127]. Cell proliferation and malignant transformation represent a switch to an angiogenic phenotype, but only in the latter is control of the cell cycle lost. Furthermore, only those hyperplastic cells which acquire angiogenic capacity undergo malignant transformation[124,126]. One model involves a tumour suppressor gene encoding the angiogenesis inhibitory factor thrombospondin, which is downregulated when cells undergo malignant transformation, allowing the angiogenic phase to commence[118]. This downregulation is under the control of the *p53* tumour suppressor gene[33]. Loss of suppressor gene sequences[128] leads to failure of inhibitory pathways with resultant tumour growth[110].

Numerous parallels between wound healing and tumour growth exist, suggesting that tumours act as 'obligate parasites' which have developed the capacity to pre-empt and subvert the wound healing response of the host as a means to acquire the stroma they need to grow and expand[129]. Normal cells involved in wound healing, such as endothelial cells and fibroblasts, develop features similar to those of malignant cells[130]. These features include increased proteolysis[131], increased motility[132] and proliferation. It is postulated that the invasive, proliferative behaviour of transformed cells may result from a functional failure of signals that usually regulate the activated behaviour of normal cells in a wound[129].

Angiogenesis and tumour metastasis

Tumour cells must detach from a primary tumour to initiate the 'metastatic cascade'[19,133]. Angiogenesis is a necessary precursor of metastasis as new proliferating capillaries have incomplete basement membranes and are 'leaky', facilitating penetrance by tumour cells[134,135]. These tumour cells must evade immune surveillance in the circulation and also at the site of secondary development, where they cross endothelium, degrade basement membrane, implant, proliferate and establish their own capillary network[19]. Angiogenesis is necessary at both the beginning and the end of the metastatic cascade. There is resultant metastatic inefficiency as only a small number of tumour cells which leave the primary tumour successfully implant at distant sites[136,137].

Effect of surgery on angiogenesis

Clinical experience and experimental evidence support the concept that the healing wound is an immunologically privileged site for metastases[25,106,138,139]. The cytokine environment that ensues in the first 24 h following surgical trauma influences the healing process for the subsequent 3 weeks[101]. Tumour growth is enhanced in healing wounds, but not in surrounding normal tissues. It has been shown that when tumour cells reach a healing colonic anastomosis or laparotomy wound within 2 h of its formation, the probability of a tumour cell leading to a metastatic deposit is increased 1000-fold compared with normal tissue[140]. Evidence showing an increased hazard rate for relapse or death in the 3 years following surgery for breast cancer, and a second peak a number of years later, supports the theory that micrometastases with a variable rate of growth are present at the time of diagnosis[141]. Surgery and subsequent healing may contribute to the genesis of recurrent disease through promotion of a proangiogenic climate which alters the dynamic equilibrium that would otherwise maintain micrometastases in a state of dormancy[20,142] (*Fig. 1*).

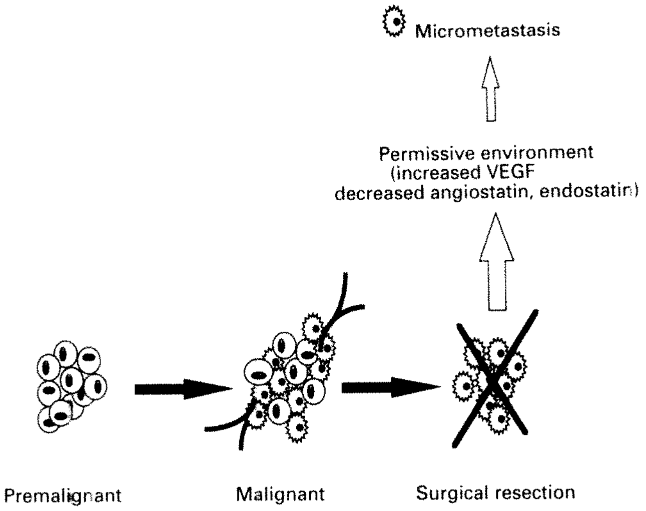

Fig. 1 Effect of surgery on micrometastases. VEGF, vascular endothelial growth factor; LPS, lipopolysaccharide

VEGF may be one of the primary links between these observations, as it is necessary to allow wound healing but may also foster growth of micrometastases through its potent proangiogenic activity. Raised circulating levels of VEGF have been identified in the early postoperative period (J. H. Harmey, unpublished observation). This may facilitate the growth and metastasis of circulating or intravasated dormant tumour cells.

Endotoxin induces angiogenesis in a dose-dependent fashion at biologically relevant doses[112]. Significant translocation of endotoxin into the peritoneal cavity and systemic circulation occurs following open surgery or air-insufflation laparoscopy[143]. It directly increases macrophage production of VEGF, a potent angiogenic factor regulating both vessel growth and permeability, an effect which also appears to extend to tumour cells[115,144]. Surgical trauma is known to increase leucocyte numbers and activity[145] and to promote tumour establishment and growth[146]. The authors' preliminary observations indicate that endotoxin introduced at the time of surgery may encourage the growth of metastases by suppression of host antitumour immune function and stimulation of proangiogenic factor release. The result is a permissive environment for tumour growth and angiogenesis.

It has been shown that the primary tumour produces circulating inhibitors of angiogenesis, called angiostatin and endostatin, which act specifically at the level of endothelial cell proliferation[121]. Within 5 days of removal of the primary tumour, angiostatin and endostatin disappear from the circulation and angiogenesis within dormant micrometastases becomes possible. This heralds a phase of rapid growth of previously dormant micrometastases[18]. Dormancy is normally maintained in tumour cells by means of a high replication rate and a correspondingly high apoptotic rate (*Fig. 2*). There is no change in the replication rate of neovascularized

metastases; however, the apoptotic rate is significantly decreased with resultant net metastatic growth[20].

Therapeutic opportunities (*Fig. 3*)

The aim of antiangiogenic treatment is to reduce and maintain tumours as small relatively dormant clusters of cells which have low metastatic potential, are more susceptible to cell-mediated immunological attack[3], and which may be more vulnerable to chemotherapy[147] and radiotherapy[148,149]. Tumour growth is associated with increased interstitial pressure due to leaky tumour vessels[150] in the absence of adequate lymphatic vessels[151]. This causes vascular compression and eventual central necrosis. As a result, tumours do not outgrow their blood supply, they compress it[152]. Antiangiogenic therapy paradoxically increases delivery of chemotherapy to a tumour[147] by reducing interstitial pressure[152]. Inhibition of angiogenesis results predominantly in a cytostatic, not a cytotoxic, effect[22,153–155], although a recent study suggests that antiangiogenic therapy may lead to tumour regression[156].

Successful antiangiogenic strategies have incorporated a wide range of antiangiogenic agents[121,157–163]. Prolonged courses of interferon α induce regression of human haemangiomatous disease[164]. Systemic administration of angiostatin induces regression of primary murine tumours of breast, colon and prostate[17]. Recombinant endostatin inhibits angiogenesis, the growth of metastases and the growth of primary tumours[123]. *In vivo* inhibition of angiogenesis using an animal model of pancreatic carcinoma has been shown to reduce tumour growth[165].

Fig. 3 Antiangiogenic interventions

Mechanisms of action

Antiangiogenic therapies may act either directly, by specifically inhibiting endothelial cell proliferation, or indirectly, by altering the cytokine microenvironment which controls angiogenesis. Tumours consist of a 'two-compartment system' in which tumour cells and endothelial cells co-exist, and produce growth factors which have paracrine effects on each other[33]. Inhibition of endothelial cell growth reduces production of tumour-promoting substances and inhibits tumour expansion. Inadequate tumour vascularization may result in tumour cell apoptosis, a genetically programmed form of cell death[36]. Dormant micrometastases are biologically active with a rate of apoptosis equal to their rate of cell proliferation[122,166]. As a result, no net growth of the metastasis occurs. Antiangiogenic therapies promote and maintain perpetual dormancy by increasing the apoptotic rate within the metastasis, hence the appellation 'dormancy therapy'.

Direct antiangiogenic agents

Angiostatin and endostatin are the only direct inhibitors of angiogenesis identified to date, and both have been shown to reduce tumour growth[121,123]. Systemic administration of endostatin, which directly inhibits endothelial cell mitogenesis, has been suggested as an ideal 'dormancy therapy'[123]. More recently, it has been reported that repeated cycles of endostatin can prevent tumour recurrence, possibly through the induction of an antiangiogenic phenotype, without leading to the problems of drug resistance which characterize many chemotherapeutic agents[156]. Hanahan[167] has suggested that direct inhibitors of angiogenesis may be subdivided into three groups. First, pure angiogenesis inhibitors, which inhibit new vessel growth but have no effect on existing tumour vessels. Second, tumour vessel toxins, which damage existing tumour vasculature and, finally, dual action agents, which combine these two effects. It appears that endostatin is a member of the last group.

Indirect antiangiogenic agents

Indirectly acting antiangiogenic therapies influence the microenvironment which regulates tumour angiogenesis and so indirectly influence endothelial cell behaviour. The majority of antiangiogenic agents currently identified belong to this group. Each tumour has a unique complex microenvironment dictated both by tumour histology and site of implantation. Additionally, within any tumour, heterogeneity arises because of variations in stromal density, tumour differentiation, hypoxia and local cytokines, among other factors. As a result, each tumour is exposed to different proangiogenic and antiangiogenic stimuli which ultimately influence net angiogenesis. It is therefore unlikely that therapeutic manipulation of a single cytokine will be sufficient to regulate tumour angiogenesis adequately. Intertumour variability suggests that therapeutic regimens based on cytokine manipulation must be custom-designed for each particular tumour type.

Maximum clinical gain may potentially be achieved by a combination of antiangiogenic interventions which influence different aspects of angiogenesis. For example, the fumagillin analogue AGM-1470 reduces endothelial cell proliferation[157]. Interferon α interferes with endothelial cell migration[168] and IL-12 inhibits angiogenesis mediated by interferon γ[169]. In contrast, suramin inhibits bFGF receptor binding in addition to a number of direct effects on endothelial cells[170], while tamoxifen inhibits VEGF-mediated endothelial cell proliferation and migration[171]. Direct manipulation of endothelial cell proliferation combined with alteration of the cytokine microenvironment may prove more effective than either approach alone.

Multimodality therapy, in which antiangiogenic strategies are combined with chemotherapeutic agents or radiotherapy, is known to be more effective than monotherapy, probably because of the combined effects on both the tumour and vascular compartments[147–149,172].

Optimal methods and timing of administration of antiangiogenic therapies have yet to be determined. Unfocused interruption of angiogenesis may potentially interfere with wound healing, menstruation and embryogenesis. Inhibitors of endothelial-specific growth factors (e.g. VEGF) have a theoretical advantage over inhibition of growth factors with more widespread targets (e.g. bFGF) because undesired non-specific interruption of mitogenesis is avoided. However, it is likely that novel methods of site-specific drug delivery, developed to administer experimental proangiogenic therapies in the treatment of ischaemic heart disease, will also be applied to the delivery of antiangiogenic agents and may help to reduce unwanted systemic effects[56]. Substantial expression of VEGF receptors is predominantly limited to the tumour vasculature. Interference with this system using monoclonal antibodies, dominant negative receptor or antisense oligonucleotides against VEGF messenger RNA offer the potential of tumour-specific inhibition of angiogenesis and subsequent metastatic growth[173]. A similar approach could be pursued for other cytokines. Developments in the field of gene therapy[174] may be harnessed to produce long-term low-grade antiangiogenic substances which maintain micrometastases in a state of dormancy.

The dosing schedule for biological antiangiogenic agents is likely to differ significantly from that for pharmaceutical agents[18]. Clinical experience with interferon α in the treatment of life-threatening haemangiomas has shown that very prolonged courses of daily therapy at optimal doses are essential for vessel involution[175]. Timing of antiangiogenic therapy in relation to other therapeutic interventions also requires clarification. For example, excision of a primary tumour results in decreased levels of the inhibitory factors angiostatin and endostatin[18], and raised circulating levels of VEGF. In the postoperative setting, this is likely to facilitate the growth and metastasis of circulating or dormant tumour cells. Therefore, manipulation of tumour angiogenesis in the perioperative period provides a tempting therapeutic opportunity. The effect of impaired angiogenesis on wound healing, however, must be clarified. A balance between the neovascularization necessary for wound healing and inhibition of neoplastic microvessel formation must be achieved.

Variability in mechanisms and control of angiogenesis at different stages in the natural history of cancer may exist. A premalignant phase is recognized for many tumours. This is also a preangiogenic phase and development of an antiangiogenic strategy which prevents the onset of angiogenesis could prevent progression to a malignant state[176]. This would require both identification of premalignant cells and development of an appropriate prophylactic antiangiogenic regimen. This is likely to differ substantially from the therapeutic approach required for primary tumours or micrometastases. For example, VEGF messenger RNA expression develops late in the course of tumour progression, is not a feature of premalignancy[28] and its manipulation is, therefore, unlikely to be of benefit in this situation. Timing of prophylactic therapy will also be critical, as angiogenesis is probably not involved in the interim stage of micrometastasis following shedding from the primary tumour, when micrometastases are distributed in organs as either single cells or small clusters with ready access to a blood supply[20]. None the less, inhibition of angiogenesis is the most promising new therapy in the treatment of malignancy. Complete understanding of the factors regulating angiogenesis and the interactions between these factors should lead to valuable new interventions. These may be combined with surgery and other modalities to improve the treatment of many solid tumours.

SURGERY TODAY
The Japanese Journal of Surgery

Digest

Professor Keizo Sugimachi, Editor-in-Chief of *Surgery Today* (*The Japanese Journal of Surgery*), has selected from the October to December 1997 issues of his journal for this quarter's digest. A digest of *BJS* for the same period written by Mr Colin Johnson, European Editor, appears in the Japanese journal.

Stomach cancer

While proximal gastrectomy is often performed for early gastric cancer in Japan, it remains unclear whether or not the procedure should be performed for advanced gastric cancer. A study[1] was designed to determine the operative indications for proximal gastrectomy in patients with gastric cancer in the upper third of the stomach. A total of 1691 patients with gastric cancer were reviewed retrospectively from hospital records covering the period from 1969 to 1994, and the clinicopathological characteristics of 82 patients who underwent proximal gastrectomy were compared with those of 150 patients who underwent total gastrectomy. Lymph node metastasis along the lower part of the stomach was observed in gastric cancers which had invaded beyond the muscularis propria of the stomach, but not in those confined to the muscularis propria. Three patients with gastric cancer that had invaded beyond the muscularis propria and metastasized to nodes along the lower part of the stomach were cured by total gastrectomy. However, there was no difference in the postoperative survival rates of patients treated with proximal gastrectomy and those treated with total gastrectomy, irrespective of tumour stage and depth of invasion. Thus, proximal gastrectomy should be performed for gastric cancer when invasion is confined to the muscularis propria of the stomach.

Rectal carcinoma

Preservation of the pelvic plexus in surgery for rectal cancer could shorten the distance between the cancer and the lateral resection margin, which may reduce the effectiveness of the operation. To clarify the indications for preserving the pelvic plexus in such surgery, the relationship of the pelvic plexus to the rectum and rectal cancer was investigated anatomically in 12 autopsy specimens and 12 surgical specimens[2]. The rectum and anus were dissected with all the pelvic organs from cadavers and transverse sections were prepared at 10-mm intervals after fixation. The location of the pelvic plexus was measured on the tissue samples and compared with that of surgical specimens from rectal cancers with concurrent resection of the pelvic plexus. The pelvic plexus was located from a mean(s.d.) of 3·3(1·2) cm above to 2·3(1·9) cm below the peritoneal reflection in the autopsy specimens. The mean distances between the muscularis propria and the pelvic plexus in the autopsy specimens and surgical specimens were 8·3(3·5) and 14·7(4·5) mm respectively ($P < 0·05$). Pelvic plexuses were located about 10 mm from the outer margin of the rectal muscularis propria. These findings indicate that concurrent resection of the plexus may be required to secure sufficient surgical clearance in pT_3 rectal cancers, especially those invading deeply beyond the muscularis propria (a_2).

The complications that may develop after preoperative intraluminal brachytherapy (IBT) and radical surgery for rectal carcinoma have been reviewed[3]. A total of 106 patients with rectal carcinoma who were given moderate (16–40 Gy) or high (40–80 Gy) doses of IBT between 1986 and 1995 were followed in the outpatient clinic. Postoperative complications developed in 34 of 87 patients in the moderate-dose group and 13 of 19 patients in the high-dose group; seven of those in the former group and five in the latter group required surgical intervention for the complication. The other patients were treated conservatively. Statistical analysis identified factors related to the incidence of complications to be the IBT dose, the field length, the time–dose factor, and the distance from above the anal verge to the distal border of the tumour. The incidence and severity of complications suggested that moderate-dose IBT was better than high-dose IBT before operation, especially when restorative operations were scheduled.

A retrospective study was conducted to identify factors related to locoregional recurrence in patients who underwent curative resection for primary rectal cancer between January 1986 and April 1994 at Ankara Oncology Hospital in Turkey[4]. A stepwise logistic regression analysis was applied for 116 patients who had complete follow-up. Age, sex, macroscopic size of the lesion, tumour location in the rectum as determined by the distance from the anal verge, obstruction at presentation, tumour histology, lymphatic invasion, venous invasion, stage according to the tumour node metastasis classification, differentiation of the tumour, surgical treatment modality, radical abdominopelvic lymphadenectomy (RAPL) and blood transfusion were used as the clinicopathological variables. Locoregional recurrent disease was found after a mean follow-up of 52 months in 28 patients (24 per cent), while the median recurrence-free period was 12 months. Univariate analysis demonstrated that age, disease stage, tumour grade, obstruction, RAPL, blood transfusion, and venous and lymphatic invasion were significant risk factors ($P < 0·05$); however, using multivariate analysis, an increased risk for the development of locoregional recurrence was found to be associated with age ($P = 0·0052$), stage ($P = 0·0379$), blood transfusion ($P = 0·0276$), obstruction ($P = 0·0035$) and RAPL ($P = 0·0069$).

Lung tumour

Between 1969 and 1995, 180 patients underwent complete resection of lung metastases during initial thoracotomy, involving the resection of 917 pulmonary nodules at 202 thoracotomy procedures[5]. The overall 5- and 10-year survival rates after metastasectomy were 46 and 30 per cent respectively. Of 111 patients who underwent segmentectomy and/or local excision, 57 had multiple metastases, 39 of whom were treated by neodymium yttrium–aluminium–garnet (NdYAG) laser after 1986 and 18 by conventional procedures before 1985. The mean number of tumours resected per patient treated with the NdYAG laser was significantly greater than that of those treated with conventional procedures. However, the survival curve of the laser-treated group was better than that of those treated conventionally. Moreover, slightly better survival was achieved in patients operated on after 1992 compared with those operated on before 1991. It is concluded that the laser technique may be warranted to afford complete resection of metastases and adequate pulmonary preservation in combination with a selective approach for thoracotomy, with careful tumour localization using the most recent high-quality computed tomography. Furthermore, a one-stage operation to control synchronous intrapulmonary and extrapulmonary malignancies may become a possible option in combination with selective adjunctive therapy.

In patients who are unable to undergo lobectomy for a small peripheral lung cancer, a partial thoracoscopic resection appears to be one valuable alternative[6]. However, since the regional lymphatics are disrupted in an anatomical fashion with a segmentectomy, it appears superior to a wedge resection. This experimental study was conducted to determine whether or not an anatomical segmental resection is feasible by thoracoscopy. A segmental resection of porcine lungs was performed using thoracoscopy. The segmental vessels were divided between ligatures. The segmental bronchus was divided by an endoscopic stapler. The intersegmental lung parenchyma was divided using a cotton dissector and a contact NdYAG laser. Forty-three pigs were divided into seven groups as follows: group 1, S^{1+2}; group 2, S^3; group 3, upper division; group 4, lower division; group 5, S^6; group 6, S^8; and group 7, S^{9+10}. The mean(s.d.) operating times ranged from 145(15) to 191(47) min. Mean(s.d.) blood loss ranged from 36(35) to 151(48) ml in all groups. The blood loss in the groups with a resection of S^6 and S^{9+10} was significantly greater than that of the other five groups. Most of the blood loss occurred during the division between the intersegmental planes. In conclusion, a thoracoscopic segmentectomy is considered to be technically feasible; however, further refinements to this technique are warranted before beginning clinical trials.

Breast tumour

The clinical and pathological features of phyllodes tumours of the breast were evaluated in a study of 118 cases: 110 benign tumours, four borderline tumours and four malignant tumours[7]. Local excision was performed in 105 patients (89 per cent) and radical mastectomy was performed in ten patients (8 per cent) as the initial treatment. Oestrogen receptor status was positive in seven of 14 cases and progesterone receptor status was positive in nine of 12 cases. Local recurrence developed in eight patients, six with benign tumours and two with malignant tumours, all of whom were treated by local excision. Of the four patients with malignant tumours, one died from lung and liver metastases 47 months after the first operation. The authors believe that excision with a sufficient free margin may be the treatment of choice for most benign or borderline phyllodes tumours, whereas an Auchincloss modified radical mastectomy or a total glandectomy with lymph node dissection is recommended for patients with malignant tumours. However, a number of problems regarding the treatment of patients with distant metastasis remain to be addressed.

To investigate the impact of the number of involved lymph nodes on survival, the data for 37 patients with breast cancer and metastases of ten or more lymph nodes, who underwent treatment between 1987 and 1995, were reviewed[8]. Based on the number of positive lymph nodes, the patients were allocated to one of three groups. The 5-year disease-free and overall survival rates for all patients were both 53 per cent. The seven patients with 26 or more positive nodes had significantly poorer survival than either the 19 patients with ten to 15 nodes or the 11 with 16 to 25 nodes, although there were no differences in survival related to the extent of nodal involvement, defined using the Japanese staging system. Patients with a 50–75 per cent frequency of metastasis, defined as the ratio of positive nodes to total resected nodes, had significantly better survival than those with a frequency of less than 50 per cent or more than 75 per cent. These results indicate that the number of involved lymph nodes is related to survival and that 25 positive nodes is a cut-off point in patients with breast cancer with ten or more positive lymph nodes.

Background Any strategy to reduce blood loss in liver resection and decrease blood transfusion would be of benefit to the patient and surgeon. This study evaluates the association of central venous pressure (CVP) with blood loss and blood transfusion during liver resection.

Methods One hundred consecutive hepatic resections in the period 1986–1996 were studied prospectively concerning CVP, volume of blood lost, and volume of blood transfused. Blood loss volume and blood transfusion were analysed for those with a CVP less than or equal to 5 cmH_2O, and greater than 5 cmH_2O. A multivariate analysis assessed potential confounding factors in the comparison.

Results The median blood loss in patients with a CVP of 5 cmH_2O or less was 200 ml ($n = 40$) and that in those with a CVP above 5 cmH_2O was 1000 ml ($n = 52$) ($P = 0·0001$). Only two of 40 patients with a CVP of 5 cmH_2O or less had a blood transfusion whereas 25 of 52 patients with a CVP greater than 5 cmH_2O required a transfusion ($P = 0·0008$). A multivariate analysis did not show confounding factors.

Conclusion The volume of blood lost during liver resection correlates with the CVP. Lowering the CVP to less than 5 cmH_2O is a simple and effective way to reduce blood loss during liver surgery.

Hepatic resection can be associated with significant intraoperative blood loss and the need for transfusion of blood and blood products[1-5], exposing the patient to the risks of transfusion. In addition, significant bleeding prolongs liver dissection and portal occlusion time, increasing the hepatic ischaemia–reperfusion injury. Any strategy that reduces blood loss during liver resection would benefit both the patient and surgeon. In addition to portal occlusion, various other devascularization manoeuvres have been designed to decrease blood loss[6-9]. Total vascular exclusion (TVE) has been used selectively but has been associated with significant risks and complications[6,7]. TVE cannot be used in all patients because of the reduction in cardiac output and consequent hypotension. Venovenous bypass can reduce the frequency of these complications but adds to the time and the complexity of the procedure.

Clamping of the structures in the lesser omentum, which occludes the inflow of blood through the hepatic artery and the portal vein to the liver[10], can be performed safely, quickly and is used widely[6,11-13]. However, the hepatic veins remain patent and bleeding may continue from them and from the sinusoids. The pressure within the sinusoids of the liver parenchyma is directly related to the pressure in the hepatic veins, which is directly related to the pressure in the central veins. The hypothesis was that a low pressure in the central veins would be accompanied by a low pressure in the hepatic veins and sinusoids, thereby decreasing blood loss during transection of the liver parenchyma. The aim of this study was to analyse the relation of central venous pressure (CVP) to blood loss during liver resection, including a multivariate analysis of possible confounding factors.

Paper accepted 28 January 1998

Patients and methods

One hundred consecutive hepatic resections, performed between 1986 and 1996, were documented prospectively. There were 48 men and 52 women with a mean(s.e.) age of 51·2(1·4) years. The indications for liver resection are outlined in *Table 1*. The liver resections were: right hemihepatectomy (Couinaud segments V–VIII) (20); left hemihepatectomy (segments II–IV) (14); right lobectomy (segments I, IV–VIII) (16); left lobectomy (segments II–III) (ten); segmentectomy (30); and subsegmentectomy (ten). Ten resections were performed in patients with cirrhosis. Data collected prospectively included age, sex, intercurrent disease, length of operation, operation performed, number of lesions resected, length of portal vein and hepatic artery occlusion, CVP, volume of intraoperative blood loss, and intraoperative and postoperative blood transfusion.

Arterial and central venous access and end-tidal carbon dioxide monitoring were used in all patients. The abdominal incision was either a reversed L or a Mercedes Benz type. A thoracic extension was used on one patient. Intraoperative ultrasonography was used routinely to identify the location and extent of disease and intrahepatic anatomy (Ultrasound SSD 248 with 7·5- and 5-MHz T-piece probes; Aloka, Tokyo, Japan). The portal triad was dissected and then clamped during parenchymal dissection (70 patients). The liver parenchyma was divided using blunt dissection in 46 instances and with the Cavitron Ultrasonic Surgical Aspirator (CUSA; Valleylab, Boulder, Colorado, USA)

Table 1 Indications for liver resection

Indication for resection	No. of patients
Colorectal metastases	52
Other metastases	15
Hepatomas	10
Hydatid disease	12
Focal nodular hyperplasia	8
Haemangiomas	3

in 54. Haemostasis was obtained with the use of monofilament polypropylene sutures, Ligaclips (Johnson and Johnson, Cincinnati, Ohio, USA) and the Argon coagulator (Bard Electro Medical System, Inglewood, Colorado, USA). The CVP was monitored continuously from a zero point at mid-atrial level using a Hewlett Packard Anaesthetic Component Monitoring System (Medical Products Group, Andover, Massachusetts, USA). The CVP was measured as the mean CVP during liver parenchymal transection only, being a plateau in nearly all patients. None of the patients with a CVP greater than 5 cmH_2O had a fluctuation below this value. In eight patients the CVP was not measured for technical reasons. The blood loss was measured by the volume in the suction bottles combined with the increase in weight of the surgical packs. Patients were transfused perioperatively as indicated on clinical grounds to maintain a haemoglobin level above 10 g/dl.

Patients were analysed in two groups according to whether their CVP was greater or less than (or equal to) 5 cmH_2O. These groups were analysed with respect to blood loss and blood transfusion requirements. In the earlier part of the study one quarter of patients had a CVP of 5 cmH_2O or less, whereas in the latter part of the study, half had a CVP of 5 cmH_2O or below.

Statistical analysis

Comparisons of length of operation and number of lesions between the two CVP groups were made using the Mann–Whitney *U* test. Analysis of blood loss was performed on log transformed data. Changes in blood loss for the two levels of CVP in the two groups of portal occlusion and non-occlusion were analysed using regression techniques fitting an interaction between CVP and portal occlusion. A similar analysis was performed with an interaction between CVP and operation type. The factors that may have contributed to blood loss, presence or absence of portal occlusion, operation type, operating time, number of lesions resected, method of liver dissection and cirrhosis were analysed by analysis of variance (ANOVA).

Results

The median blood loss for all liver resections was 450 (range 25–8000) ml. Only two of the 40 patients with a CVP of 5 cmH_2O or less had a blood transfusion (500 ml, 1000 ml), while 25 of the 52 patients with a CVP greater than 5 cmH_2O required a blood transfusion (median transfusion 1500 (range 500–8000) ml). Blood loss and transfusion requirements were significantly less in patients with a CVP less than or equal to 5 cmH_2O during resection than in those with a pressure greater than 5 cmH_2O (*Table 2*). Possible confounding factors that may have contributed to blood loss were evaluated by ANOVA. These included the presence or absence of portal occlusion, the operation type, the operating time, the number of lesions resected, the method of liver dissection and cirrhosis.

Fig. 1 relates blood loss to CVP, with and without portal triad occlusion. Without portal triad occlusion the mean(s.e.) blood loss in patients with a CVP of 5 cmH_2O or less was 167(33) ml and in those with a CVP greater than 5 cmH_2O it was 1833(515) ml ($P<0{\cdot}001$). Similarly, with portal occlusion there was a significant difference in mean blood loss between the two groups: 400(126) and 1344(264) ml respectively ($P<0{\cdot}001$). An analysis of the effect of CVP within each type of liver resection for patients with and without cirrhosis, ultrasonic dissection or a clamp-fracture dissection technique and for the length of the operation showed a significant reduction in blood loss for all procedures in patients with a CVP less

Table 2 Comparison of blood loss and blood transfusion requirements in patients with a central venous pressure less than or greater than 5 cmH_2O

	Median blood loss (ml)	Blood transfusion (ml)	Total no. of patients	No. of patients transfused
CVP (cmH_2O)				
≤5	200	0–1000	40	2 (5)
>5	1000	0–8000	52	25 (48)
P	<0·0001	0·0008		

Values in parentheses are percentages. CVP, central venous pressure (Mann–Whitney *U* test)

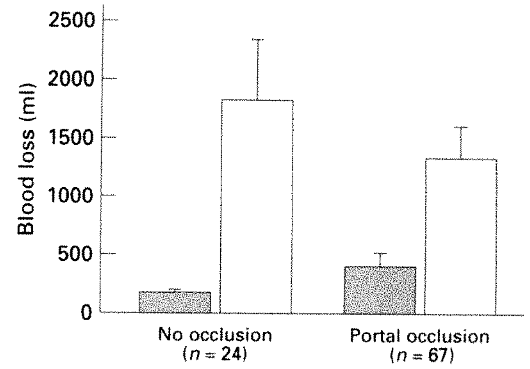

Fig. 1 Mean(s.e.) blood loss during liver resection with and without portal triad occlusion. There was a significant difference in blood loss between patients with a central venous pressure (CVP) greater than 5 cmH_2O (□) and those with a CVP of 5 cmH_2O or less (▨), both with and without portal occlusion ($P<0{\cdot}001$, Mann–Whitney *U* test)

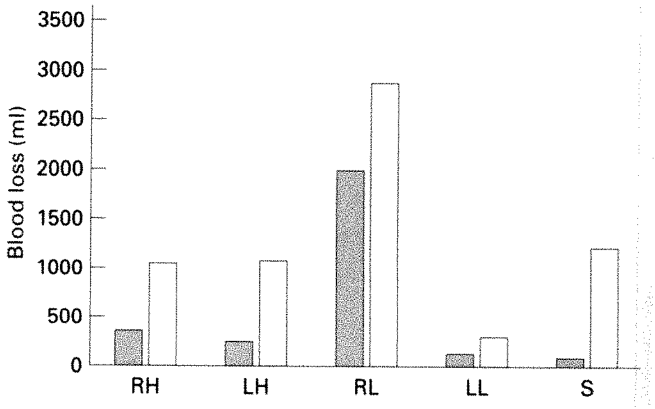

Fig. 2 Mean blood loss by operation type in patients with central venous pressure above 5 cmH_2O (□) and less than or equal to 5 cmH_2O (▨). There was significantly less blood loss in the latter patients for each type of liver resection except left lobectomy (LL; Couinaud segments II–III). RH, right hemihepatectomy (segments V-VIII); LH, left hemihepatectomy (segments II–IV); RL, right lobectomy (segments I, IV–VIII); S, segmentectomy or subsegmentectomy. $P<0{\cdot}05$ or better for RH, LH, RL and S (ANOVA)

than or equal to 5 cmH_2O (*Fig. 2*), significant for all operative types except left lobectomy where the numbers involved were too small to analyse.

Discussion

This study showed a significant reduction in blood loss and blood transfusion requirements in patients undergoing liver resection when the CVP was maintained at less than or equal to 5 cmH_2O during parenchymal dissection. This result was not influenced by the presence or absence of portal occlusion, the resection type, the length of operation, the number of lesions resected, the method of liver dissection or the presence or absence of cirrhosis. The principle of maintaining a low CVP to decrease blood loss has been alluded to in the literature[11-14], but until recently had little published support. A preliminary report showed a significant reduction in blood loss after instituting a 'low CVP' policy comparing patients studied with historical controls[14]. However, correction for other factors that may have influenced blood loss was not made, making a firm correlation of CVP to blood loss difficult. A study of 20 patients showed strong correlation between three bands of CVP (less than 6, 6–12, greater than 12 mmHg) and operative blood loss[15]. These authors did not examine other risk factors in their study.

The potential for air embolism, while maintaining a low CVP during division of the liver, is significant. A negative CVP can rapidly allow large volumes of air through small or unrecognized lacerations of the hepatic veins. This is unlikely with a positive CVP. Steps were taken to avoid an air embolus in this series by immediate oversewing of any holes in the hepatic veins during parenchymal dissection. For early recognition of air embolus, end-tidal carbon dioxide was monitored continuously. Any abrupt drop in end-tidal carbon dioxide would suggest air embolus, especially if associated with haemodynamic change. A minor fall in end-tidal carbon dioxide was common, but a small air embolism was suspected in only two patients.

The results of this study have altered the authors' practice of liver resection. The CVP during parenchymal resection is now kept between 2 and 5 cmH_2O, and patients are not fluid volume loaded at operation. A glyceryl trinitrate infusion is commenced at the start of the resection, to lower CVP if necessary, and can be continued throughout the liver parenchymal division phase. The patient is positioned head up or diuretics also used as required.

Maintaining a low CVP throughout hepatic resection reduces blood loss and blood transfusion requirements. This is particularly evident when the area of parenchymal resection is larger, such as a hemihepatectomy or non-anatomical resection. Lowering the CVP is a simple and effective way to reduce blood loss during liver surgery.

Background The pathogenesis of hepatic ischaemia–reperfusion injury is incompletely understood. This study examined the effects of reperfusion with congested portal blood on ischaemia–reperfusion injury of the liver following Pringle's manoeuvre, as monitored by heat shock protein (HSP) 72 production in rat liver tissue.

Methods Rats were randomized to three groups. In group 1 hepatic ischaemia with portal congestion was induced by Pringle's manoeuvre for 15 min; in group 2 Pringle's manoeuvre was applied for 15 min with an extracorporeal portasystemic shunt; and in group 3 the superior mesenteric vein was occluded for 15 min. The production of HSP72 in liver tissue was measured by Western blotting at 48 h after each intervention. Conventional parameters for hepatic function were examined at 1, 3 and 48 h after reperfusion.

Results There was marked HSP72 expression in group 1, but not in group 2 or 3, showing that a combination of liver ischaemia and reperfusion of congested portal blood is required to induce strong expression of HSP72 in the tissue. On the other hand, biochemical parameters were raised equally in both groups 1 and 2, reflecting a similar degree of ischaemic hepatocyte injury.

Conclusion The additional stress impact of temporary portal occlusion upon ischaemia–reperfusion injury of the liver was clearly detected by *in situ* hepatic HSP72 production in this study.

Application of Pringle's manoeuvre, with cross-clamping of the hepatoduodenal ligament, has been shown to reduce blood loss during hepatic parenchymal resection[1]. The disadvantage, however, is that prolonged total inflow occlusion may induce unwanted hepatocyte injury. It has been demonstrated repeatedly in the clinical setting that continuous Pringle occlusion in excess of 1 h, particularly where there is underlying cirrhosis, may induce profound hepatic dysfunction, with the induction of liver failure and death of the patient in some instances[2–6].

Although the pathogenesis of hepatic ischaemia–reperfusion injury after Pringle's manoeuvre is incompletely understood, there are three phases of injury: (1) hepatic ischaemia, (2) portal venous congestion and (3) reperfusion with arterial and congested portal blood. The reperfusion phase may be the dominant phase of injury. It has been revealed that reactive oxygen species and some chemical mediators activated during recirculation play an important role in the development of liver injury after ischaemia[7–10]. Prolonged occlusion of the portal system leads to marked congestion of the bowel wall, with breakdown of the intestinal barrier. Subsequent translocation of bacteria, or release of chemical inflammatory mediators or reactive oxygen species in portal blood, may be toxic to the liver. It is proposed that congested portal blood containing pathogens and activated inflammatory mediators may augment ischaemia–reperfusion injury of the liver. However, the specific roles of ischaemia, portal congestion and reperfusion have not been well documented in previous studies. Indeed, there is only indirect evidence to suggest a significant role for portal congestion in hepatic injury, as sensitive markers have not been available previously[11].

The discovery of the heat shock protein (HSP) gene family with its induction and hyperexpression after liver injury has been an exciting development in the science of liver injury. It was reported previously that HSP72 could be induced in liver tissue after normothermic ischaemia and reperfusion injury[12–14]. HSP72 is known to be one of the most fundamental stress proteins. The HSP70 gene family is highly conserved, present even in invertebrates, and is considered to be important in maintaining cellular homoeostasis and in increasing the chance of survival[15,16].

In the present study, the production of HSP72 was compared in three groups of rats, to determine the influence of hepatic reperfusion with congested portal blood on the development of ischaemia–reperfusion injury: (1) after 15 min of Pringle inflow occlusion and reperfusion with congested blood; (2) after a similar period of Pringle occlusion following creation of a temporary portasystemic shunt to prevent congestion; and (3) after 15 min of occlusion of the superior mesenteric vein only, without hepatic inflow occlusion, to determine the effects of portal congestion alone on the non-ischaemic reperfused liver.

Materials and methods

Male Wistar rats weighing 200–300 g were housed in an air-conditioned room (23–25°C) and exposed to 12-h light–dark cycles. Standard rat chow and water were provided *ad libitum*, according to the animal protection guidelines of Kyoto

Paper accepted 6 January 1998

University. Rats were premedicated with intramuscular atropine sulphate injection (0·05 mg per kg body-weight) and anaesthetized with intraperitoneal pentobarbital sodium (40 mg per kg body-weight) for all operative procedures.

Rats were assigned randomly to three groups. In the first group (group 1), the abdomen was opened through a median laparotomy and the liver was detached from its ligaments. Total hepatic inflow occlusion with portal congestion was induced by clamping the hepatoduodenal ligament for 15 min with a microvascular clamp. Fifteen minutes of hepatic ischaemia was chosen for this study, since further prolonged periods of portal occlusion cannot be tolerated in the rat. In group 2, the abdomen was opened and the liver was mobilized in an identical manner. An extracorporeal portasystemic shunt was then created, by cannulating the caecal branch of the superior mesenteric vein and the external jugular vein, using polyethylene tubing (0·58 mm inner diameter, 200 mm long; Dural Plastics, Sydney, Australia) primed with 0·04 ml heparinized saline solution (250 units/ml). The liver was then exposed to a 15-min warm ischaemic insult by microvascular clamping of the hepatoduodenal ligament, but portal congestion was prevented by the extracorporeal shunt. In group 3, the abdomen was opened in an identical manner, and the superior mesenteric vein was occluded with a microvascular clamp for 15 min. Under these conditions, arterial and portal hepatic inflow from the splenic vein were maintained, and mesenteric congestion without hepatic ischaemia was achieved. During all the above interventions the abdomen was closed temporarily and an electric heating pad was placed beneath the animals to keep the rectal temperature at 35–37°C. Release of the microvascular clamp allowed immediate hepatic reperfusion, and blood and liver tissue samples were obtained at specified intervals.

For the detection of HSP72 production in the liver tissue at 48 h after each intervention, Western blot analysis was performed according to methods reported previously[17–19].

For the evaluation of tissue adenosine 5′-triphosphate (ATP) levels, liver tissue was sampled by freeze-clamping at 1 h ($n = 6$), 3 h ($n = 6$) and 48 h ($n = 6$) after reperfusion. Samples of frozen tissue (approximately 400 mg) were stored in liquid nitrogen pending assay. Each sample was homogenized with 2 ml of perchloric acid 0·33 mmol/l and the extract was centrifuged. The supernatant was neutralized with 69 per cent potassium carbonate solution (pH 5·5–6·0) and centrifuged again. Adenine nucleotide levels were assayed enzymatically in the supernatant[20,21]. Blood samples were taken from the aorta at 1 h ($n = 6$), 3 h ($n = 6$) and 48 h ($n = 6$). The serum concentrations of alanine aminotransferase (ALT) and lactic dehydrogenase (LDH) were assayed on a standard biochemistry autoanalyser. After sampling, rats were killed humanely under anaesthetic.

Values are expressed as mean(s.d.). Statistical analysis was performed by one-factor analysis of variance (ANOVA) with Bonferroni/Dunn *post hoc* comparisons. $P < 0·05$ was considered to be significant.

Results

The accumulation of inducible HSP72 in rat liver tissue after 48 h of reperfusion in each group is shown in *Fig. 1*. In normal liver tissue and tissue from group 3, HSP72 was not detectable. In groups 1 and 2, where rats were subjected to hepatic ischaemia, HSP72 was induced. HSP72 was markedly overexpressed in group 1 but its accumulation in group 2 was minimal.

Changes in ATP concentration in the liver tissue at 1, 3 and 48 h after reperfusion are shown in *Fig. 2*. The ATP levels in groups 1 and 2 were significantly lower than those in group 3 at 1 and 3 h after reperfusion but there were no differences between groups 1 and 2. At 48 h after reperfusion, there were no significant differences between the three groups.

Changes in serum ALT and LDH levels in each group are shown in *Fig. 3*. At 1 h after reperfusion, ALT levels in groups 1 and 2 rose to over 4000 units/l, while the mean value in group 3 was 300 units/l, significantly lower than that in group 1 or 2. At 3 h after reperfusion, ALT concentration in group 1 remained raised, but levels in groups 2 and 3 recovered to 2700 and 200 units/l respectively. LDH levels increased to 40 000 units/l in both groups 1 and 2, but the mean value in group 3 was less than 10 per cent of that in groups 1 and 2. The pattern of LDH increase after reperfusion was similar to that of ALT.

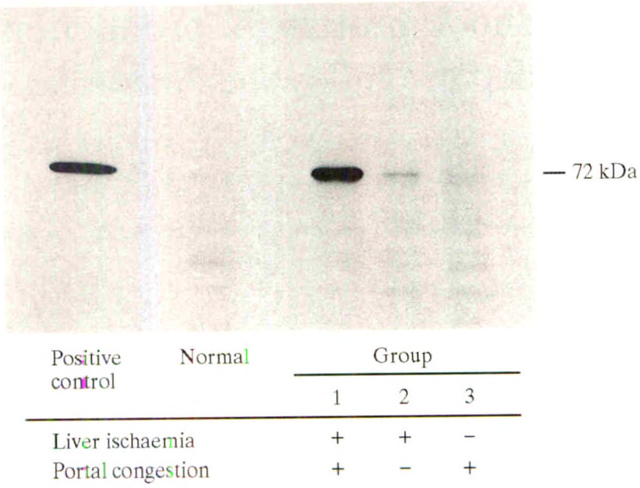

Fig. 1 Heat shock protein (HSP) accumulation in the rat liver after 48 h of reperfusion in each group compared with that in normal liver (5 μg protein per lane). HSC70, which contains inducible HSP72 in approximately 10 per cent, was used as a positive control (0·2 μg per lane)

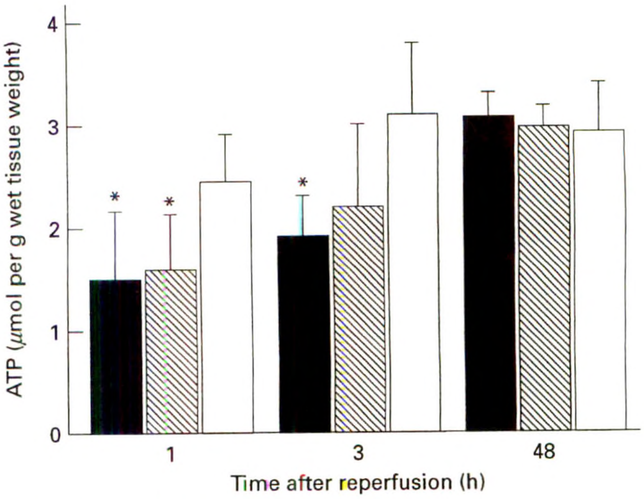

Fig. 2 Changes in adenosine 5′-triphosphate (ATP) concentration in liver tissue at 1, 3 and 48 h after reperfusion in groups 1 (■), 2 (▨) and 3 (□). Values are expressed as mean(s.d.). The ATP levels in groups 1 and 2 were significantly lower than that of group 3 at 1 h after reperfusion (group 1 *versus* group 3: $F = 4·90$, 15 residual d.f., $P = 0·02$ (analysis of variance (ANOVA)); $P = 0·01$ (*post hoc* comparison)) and at 3 h after reperfusion (group 1 *versus* group 3: $F = 5·59$, 15 d.f., $P = 0·02$ (ANOVA); $P = 0·01$ (*post hoc* comparison)), but there were no differences between groups 1 and 2 (1 h, $P = 0·75$; 3 h, $P = 0·41$). At 48 h after reperfusion, there were no significant differences between the three groups ($F = 0·26$, 15 d.f., $P = 0·78$). $^*P < 0·05$ *versus* group 3 (ANOVA)

In the comparison between ALT and LDH levels in groups 1 and 2, there was a trend towards higher transaminase levels in group 1 but it was not statistically significant (ALT: 1 h, $P=0{\cdot}46$; 3 h, $P=0{\cdot}05$. LDH: 1 h, $P=0{\cdot}31$; 3 h, $P=0{\cdot}16$). By 48 h, ALT and LDH levels were no different between the groups (ALT: group 1, 226(155) units/l; group 2, 181(103) units/l; group 3, 66(36) units/l; $F=3{\cdot}43$, 15 d.f., $P=0{\cdot}06$. LDH: group 1, 588(265) units/l; group 2, 476(248) units/l; group 3, 450(302) units/l; $F=0{\cdot}43$, 15 d.f., $P=0{\cdot}66$).

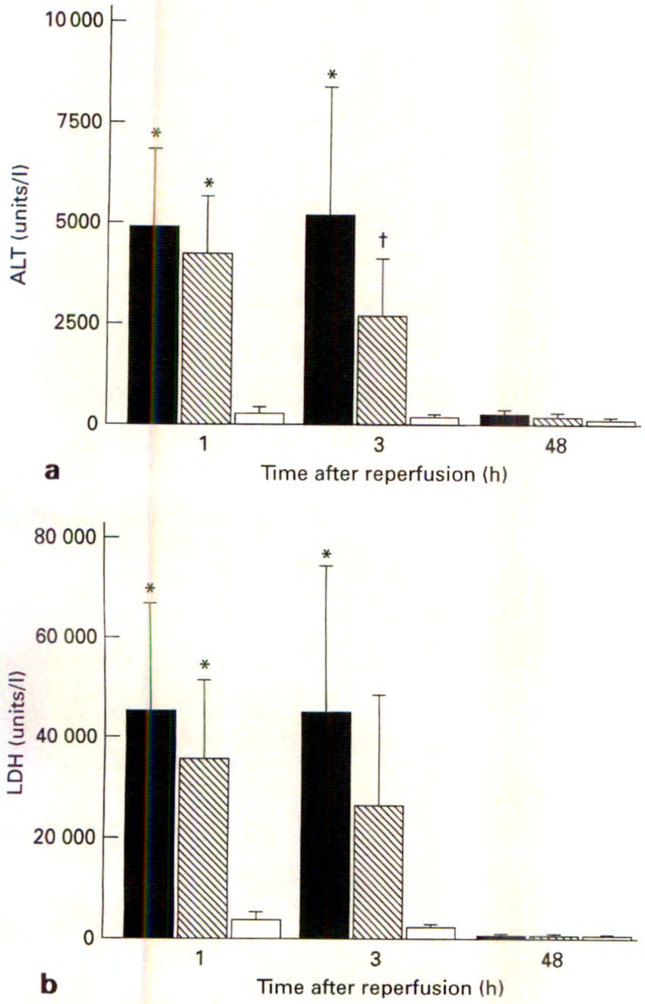

Fig. 3 Changes in **a** serum alanine aminotransferase (ALT) level and **b** serum lactate dehydrogenase (LDH) level at 1, 3 and 48 h after reperfusion in groups 1 (■), 2 (▨) and 3 (□). Values are mean(s.d.). At 1 h after reperfusion, the ALT level in groups 1 and 2 increased significantly more than that in group 3 ($F=17{\cdot}90$, 15 d.f., $P<0{\cdot}001$ (analysis of variance (ANOVA)); $P<0{\cdot}001$ (group 1 *versus* group 3), $P<0{\cdot}001$ (group 2 *versus* group 3) (*post hoc* comparison)). At 3 h after reperfusion, ALT concentration in group 1 remained raised, but levels in groups 2 and 3 decreased ($F=9{\cdot}05$, 15 d.f., $P=0{\cdot}003$ (ANOVA); $P<0{\cdot}001$ (group 1 *versus* group 3), $P=0{\cdot}05$ (group 2 *versus* group 3) (*post hoc* correction)). LDH levels also increased remarkably in both groups 1 and 2, but mean values in group 3 were less than 10 per cent of those in groups 1 and 2 ($F=11{\cdot}82$, 15 d.f., $P<0{\cdot}001$ (ANOVA); $P<0{\cdot}001$ (group 1 *versus* group 3), $P=0{\cdot}003$ (group 2 *versus* group 3) (*post hoc* correction)). The pattern of LDH increase after reperfusion was similar to that of ALT (at 3 h of reperfusion: $F=6{\cdot}00$, 15 d.f., $P=0{\cdot}01$ (ANOVA); $P=0{\cdot}004$ (group 1 *versus* group 3), $P=0{\cdot}07$ (group 2 *versus* group 3) (*post hoc* correction)). $^*P<0{\cdot}01$, $^\dagger P<0{\cdot}05$ *versus* group 3 (ANOVA)

Discussion

HSP72 is an ubiquitous protein, highly conserved throughout the evolutionary scale, which has been shown to be induced rapidly in response to stress. It appears to be an important adaptational response to hibernation, and is believed to constitute an endogenous protective response to injury. Blockade of this pathway has been shown to augment susceptibility to hypoxic injury[22]. Ischaemic preconditioning of tissue and organs, with short periods of ischaemia preceding the final insult, has been shown to protect cells from injury, and a likely mechanism of protection includes HSP72 induction. Hyperexpression of HSP72 has been shown to protect cultured neurones from heat shock[23], and may decrease cardiac infarct size in mouse models of myocardial ischaemia[24]. Regulation of HSP72 production is mediated via activation and binding of a heat shock transcription factor to a specific sequence of the promoter, called the heat shock element[25]. It was previously shown that HSP72 induction by heat stress was able to protect significantly against subsequent warm ischaemic liver injury in the rat[26].

The present study addressed the role of reperfusion of the ischaemically injured liver with congested portal blood after temporary Pringle inflow occlusion. It was hypothesized that portal congestion, with its potential for induction of bacterial translocation, endotoxin and other immune activation pathways, may constitute a 'second-hit' insult to the ischaemically injured liver. Intrahepatic production of HSP72 was used as a highly sensitive indicator of liver injury in this study.

A limited period of 15 min of total hepatic inflow occlusion (group 1) caused marked serum increases in ALT and LDH levels at 1 and 3 h after reperfusion, which returned to baseline within 48 h of surgery, indicating that significant, but reversible, hepatocellular injury had been induced. Creation of a temporary portasystemic shunt to relieve portal congestion followed by Pringle occlusion (group 2) also led to marked increases in ALT and LDH levels, with a non-significant trend toward lower transaminase levels compared with group 1. Intrahepatic stores of ATP were reduced similarly early after injury, with complete recovery by 48 h.

In terms of HSP72 induction, there was high expression in the livers of group 1 animals, where ischaemic injury was followed by reperfusion with congested portal blood. Where a portasystemic shunt was used, however, there was minimal HSP72 expression at 48 h. It would appear from the data, therefore, that a limited period of 15 min of warm ischaemia followed by hepatic reperfusion with non-congested portal blood was an inadequate stimulus for HSP72 synthesis in the rat liver. In contrast, Tacchini *et al.*[27] reported that inflow occlusion of the partial liver for the longer period of 60 min induced the expression of HSP70 messenger RNA (mRNA) in the ischaemic lobe of rat livers. In their experiment, portal circulation to the non-ischaemic liver lobes was maintained during hemiocclusion of the hepatic inflow and portal congestion was therefore avoided. Nevertheless, the stress response was triggered only by ischaemia. It would appear that, in the absence of portal congestion, marked HSP72 induction occurs only when severe parenchymal damage has been initiated by prolonged ischaemia.

The present study has demonstrated an important synergistic interaction of congested portal blood reperfusion and as little as 15 min of Pringle-induced ischaemia on the production of HSP72 in liver tissue. Schoeniger *et al.*[13] reported that activation of HSP72 gene transcription in porcine liver after Pringle-induced ischaemia did not occur until after restoration of blood flow. They showed that the reperfusion phase led to maximal transcription of HSP72 mRNA, which was found to be highly dependent on the generation of superoxide anions. Although this report suggests the importance of reperfusion injury in the stress response of the liver after ischaemia, the role of portal blood pooling during reperfusion was not addressed specifically. The aetiological mechanism of ischaemic injury synergy with congested portal blood is presumed to be complex and multifactorial. It is likely that pathogen translocation, endotoxin release and immune activation may all play a part in exacerbating ischaemia–reperfusion injury in the liver. A key intermediate may be production of reactive oxygen species in portal blood after oxidative stress, which is known to activate the heat shock response[28,29]. Free radical generation in portal blood during portal occlusion may be particularly harmful to the ischaemically injured liver during reperfusion. Increased xanthine oxidase activity in the portal plasma and increased permeability of the small intestinal wall may be other factors leading to heightened injury after ischaemia and reperfusion[7]. Moreover, bacterial translocation caused by congestion of the portal vein leads to release of both endotoxin and a variety of cytokines[9], which may also cause HSP induction, as speculated by some authors[16,30–33]. Results for the control group (group 3), in which superior mesenteric occlusion was induced in the absence of liver ischaemia, clearly indicated that hepatic perfusion with portal toxins alone was insufficient to induce HSP72 production.

The present study has demonstrated that HSP72 might prove to be a more useful marker than transaminase release or hepatic ATP content in evaluating the degree of hepatic injury after ischaemia–reperfusion. A drawback of HSP72 monitoring is that *de novo* synthesis may limit assessment of dynamic changes in acute liver injury. To overcome this shortfall, examination of HSP72 mRNA may be of more relevance in clinical applications.

Although a 15-min Pringle's manoeuvre is not fatal for Wistar rats, the stress response induced by reperfusion with congested portal blood was a highly potent stimulator of HSP72 production compared with non-congested reperfusion. More prolonged periods of inflow occlusion may cause further accumulation of pathogens in the portal system leading to fulminant liver failure and early death in the rat. The failure of intermittent portal triad cross-clamping in protection from injury was confirmed by analyses of arterial ketone body ratio and liver-related enzyme levels in serum[11]. According to differences in mechanisms of stress response with HSP72 synthesis, alteration in mitochondrial energy status of hepatocytes, and liberation of liver enzymes into serum during and after ischaemia–reperfusion, HSP72 synthesis seems to be an early event in cellular dysfunction and its action may be more sensitive to this type of injury than arterial ketone body ratio or conventional parameters of liver damage.

In conclusion, the deleterious effect of warm ischaemia–reperfusion in the liver tissue induced by short-term Pringle's manoeuvre was attributable principally to synergistic toxicity from reinflow of congested portal blood. The influence of congested portal blood on ischaemia–reperfusion injury was detected clearly using HSP72, which is now advocated as a highly sensitive parameter of injurious stress to the liver.

Short note

Prospective randomized trial of 5- and 10-mm epigastric ports in laparoscopic cholecystectomy

M. GOLDER and M. RHODES

Department of Surgery, Gastrointestinal Unit, Norfolk and Norwich NHS Trust Hospital, Norwich NR1 3SR, UK
Correspondence to: Mr M. Rhodes

Laparoscopic cholecystectomy has traditionally been undertaken with two 10-mm ports, one at the umbilicus and the other in the epigastrium. Two further 5-mm ports are placed along the line of a Kocher's incision. There has been a recent drive to reduce port sizes first with the introduction of a 5-mm laparoscope and then with equipment designed for 3- and 2-mm port sizes[1,2]. Unlike the introduction of new medication[3], many variations in surgical technique are introduced without a prospective randomized controlled trial to assess their efficacy. There appear to be theoretical reasons why reducing port sizes might reduce pain and speed recovery after laparoscopic cholecystectomy. A prospective randomized trial has therefore been conducted to assess the impact on patients of reducing the epigastric port size to 5 mm.

Patients and methods

Over a 4-month period, 60 consecutive patients were invited to be randomized to either traditional '10-mm' laparoscopic cholecystectomy or '5-mm' laparoscopic cholecystectomy. Patients in the 5-mm group had the cystic duct secured with a 5-mm clipper (Ethicon, Cincinnati, Ohio, USA) and the gallbladder removed from the umbilicus under direct vision using a 5-mm, 30° laparoscope (KeyMed, Southend-on-Sea, UK), placed in the epigastric port. Standard dressings were applied at the end of operation to ensure that ward staff could not differentiate between the two groups. Patients received a standardized anaesthetic and a record was kept of total morphine consumption, and pain scores at 1, 3, 6 and 18 h after surgery. Discharge from hospital and date of return to normal activity or work was also recorded. All data were collected by the first two authors without prior knowledge of which operation had been undertaken.

Results

Of 60 patients approached, three refused to take part in the study. Four further patients refused to have pain scored after operation. Of 53 remaining patients, 26 underwent 10-mm laparoscopic cholecystectomy and 27 5-mm laparoscopic cholecystectomy. The results are shown in *Table 1*. There were no significant differences in any of the variables measured. Complications occurred in five patients in the 5-mm group; four required conversion to more than one 10-mm port because of dense adhesions and thick-walled gallbladders while one patient in this group required conversion to open surgery. There were no wound infections requiring antibiotics or hernias in either group during the 6 months after surgery.

Table 1 Age, duration of operation, pain scores, analgesia consumption, hospital stay and return to work after 5-mm and 10-mm laparoscopic cholecystectomy

	10 mm	5 mm	P*	95% confidence interval
Age (years)	58 (30–80)	52 (28–73)	n.s.	—
Duration of operation (min)	70 (43–108)	73 (33–125)	0·86	−13 to 13
Pain score				
1 h	3·2 (0–9·9)	3·0 (0–9·9)	0·87	−1·8 to 1·5
3 h	3·2 (0–9·9)	3·0 (0–7·0)	0·47	−2 to 1
6 h	2·0 (0–9·9)	3·0 (0–8·0)	0·15	−2 to 0·1
18 h	3·0 (0–5·0)	1·0 (0–7·8)	0·17	5 to −2
Total morphine (mg)	10 (0–34)	10 (0–46)	0·58	−6 to 5
Hospital stay (h)	24 (14–72)	24 (17–72)	0·97	−6 to 5
Time to return to normal (days)	4 (1–14)	3 (1–7)	0·19	−6 to 4

Values are median (range). n.s., Not significant. *Mann–Whitney *U* test

Discussion

Laparoscopic cholecystectomy is inherently a procedure associated with a short hospital stay and low pain scores in the postoperative period. Significant improvement in pain scores and a reduction in opiate usage can be achieved by using diclofenac sodium[3]. This prospective randomized study has failed to show any significant benefit in postoperative pain, opiate consumption or return to normal activity as a result of a reduction in the epigastric port size from 10 to 5 mm. Power calculations based on previous work[3] had suggested that this sample size would be large enough to detect significant changes in pain scores or analgesic requirements.

It is highly likely that at least one 10-mm port will be required for laparoscopic cholecystectomy in the UK, so that thick-walled and stone-laden gallbladders may be removed from the peritoneal cavity. This being so, then the first choice for reducing port sizes would be the 10-mm epigastric port. Reduction in size avoids the need for suture closure of the deep fascia in the epigastrium and may have some cosmetic benefits. It does not, however, have significant clinical benefits in terms of pain relief or analgesia consumption. Pressure to further reduce port sizes to 2 or 3 mm should be resisted unless there is objective clinical benefit, particularly as instruments designed for such ports are not as effective for handling severely diseased gallbladders as 5- or 10-mm instruments (personal observation). If additional expense is involved in the reduction in port sizes (which was not the case in this study), or if instrument effectiveness is

---

Paper accepted 2 February 1998

compromised in a drive for ever smaller ports, there should be objective benefits to the patient in terms of postoperative pain and overall recovery before a change to smaller ports can be recommended.

Background Peripheral intrahepatic cholangiocarcinoma (PIC) is an intrahepatic primary liver neoplasm which is clinicopathologically distinct from hepatocellular carcinoma and major duct cholangiocarcinoma. The clinical outcome after resection of these rare tumours is not well documented.

Methods Review of the hepatic database and tumour registry at Memorial Sloan-Kettering Cancer Center identified 32 cases of PIC resected for cure over a 23-year period. Intrahepatic cholangiocarcinomas with major bile duct involvement were excluded from this analysis. Demographics, pathological features, biochemical markers, operative results and survival were analysed.

Results The majority of patients presented with abdominal pain ($n = 19$). Only two patients had pathological evidence of hepatic cirrhosis. Serum marker levels included α-fetoprotein (AFP; median 3·7 (range 0–225) ng/ml) and carcinoembryonic antigen (CEA; median 1·6 (range 0–30) ng/ml). Type of hepatic resection included: wedge ($n = 2$), lobectomy ($n = 14$) and extended lobectomy ($n = 16$). There was one postoperative death. Median follow-up time was 27 months. Median survival was 59 months with an actuarial 5-year survival of 42 per cent. Vascular invasion and intrahepatic satellite lesions were predictors of worse survival ($P < 0·05$).

Conclusion PIC is a rare hepatic primary tumour, which usually presents in non-cirrhotic livers with a normal serum AFP and CEA level. In selected patients, complete surgical resection can be performed safely and is associated with long-term survival.

Bile duct tumours include a spectrum of diseases defined by location and histology. Cholangiocarcinomas may arise in the distal extrahepatic bile ducts, proximal intrahepatic major ducts (Klatskin tumours), as well as from peripheral intrahepatic biliary radicals. Each location has its own presentation and natural history. In addition to prognosis, distinction between the three tumour sites is important in terms of treatment planning. The surgical option for distal cholangiocarcinomas is usually pancreaticoduodenectomy[1]. For proximal or hilar bile duct lesions, major bile duct excision with or without hepatic resection is indicated[2]. For peripheral intrahepatic cholangiocarcinoma (PIC), hepatic resection is usually indicated, occasionally requiring extrahepatic bile duct excision for complete tumour clearance[3].

Of the three, PIC is the least common and has been referred to by a variety of terms including cholangiocellular carcinoma, cholangiolar carcinoma or peripheral cholangiocarcinoma. Although rare, PIC is the second most common hepatic primary tumour after hepatocellular carcinoma. Pathologically, these tumours represent a transition from hepatocellular to extrahepatic cholangiocarcinoma. Importantly, PIC is clinicopathologically distinct from hepatocellular carcinoma and major duct cholangiocarcinoma, and the clinical outcome after resection of these rare tumours is not well documented. The current paper reports 32 patients with PIC who underwent surgical resection at a tertiary referral centre, in order to define perioperative results and to identify predictors of long-term survival.

Paper accepted 30 January 1998

Patients and methods

Review of the authors' prospective hepatic database and tumour registry identified 32 cases of PIC resected for cure over a 23-year period. Patients were selected based on the absence of extrahepatic disease and technical ability to undergo resection. Postoperative chemotherapy was not administered routinely. Intrahepatic cholangiocarcinomas with any major bile duct involvement were excluded from this analysis. All pathological specimens were reviewed to confirm the diagnosis of PIC. Tumours with minimal hepatocellular features were included (PIC, mixed type; $n = 3$). Tumours were classified according to the criteria of the American Joint Commission on Cancer[4].

A right lobectomy included resection of hepatic segments V, VI, VII and VIII. The inclusion of segment IV in the resected specimen constituted an extended right lobectomy (right trisegmentectomy). A left lobectomy included segments II, III and IV, and the addition of segments V and VIII was defined as an extended left lobectomy (left trisegmentectomy).

Medical records were reviewed and the following factors were analysed: (1) demographics, (2) symptoms at presentation, (3) biochemical markers and (4) intraoperative factors, including operative time, blood loss and transfusion requirements. Outcome measures included length of hospital stay, operative deaths and overall survival.

Data are expressed as median (range). Survival was calculated by the Kaplan–Meier method and compared by log rank test with statistical significance defined as $P < 0·05$.

Results

Patient characteristics

Thirty-two patients underwent resection for PIC (five from 1972 to 1987, six from 1988 to 1991 and 21 cases from 1992 to 1995). There were ten men and 22 women of median age 69 (49–82) years. None of the patients presented with intrahepatic stones or parasitic infections. The most common symptom at presentation was abdominal pain ($n = 19$). Only one patient presented with jaundice. Eight patients had a history of hepatitis. There were equal numbers ($n = 12$) of primary tumours in the right and left lobes. Eight patients presented with tumours involving both lobes.

The majority of patients presented with serum bilirubin levels within the normal range (0–1 mg/dl), with a median value of 0·5 (0·3–18·3) mg/dl. Serum α-fetoprotein (AFP; normal range 0–10 ng/ml) levels were raised in four of 20 patients (median 3·7 (0–225) ng/ml). Carcinoembryonic antigen (CEA; normal range 0–5 ng/ml) levels were raised in two of 18 patients (median 1·6 (0–30) ng/ml).

Operative results

Of the 32 patients, two underwent wedge resection, 14 underwent lobectomy and 16 patients required an extended hepatic lobectomy (trisegmentectomy) for tumour clearance. All resections were macroscopically complete. The median operating time was 4·5 (2·3–8·5) h. The median operative blood loss was 1000 (200–5900) ml and median blood transfusion was 2 (0–11) units of packed red blood cells. One patient died 14 days after operation from sepsis. The median hospital stay was 11 (3–81) days.

Pathology

The median tumour size was 8·0 (3–16) cm. Four patients had positive lymph nodes. Resection margins were positive in six patients. Satellite lesions were detected in 13 patients, perineural invasion in seven and vascular invasion in ten patients. Only two patients had pathological evidence of cirrhosis. Microscopic vascular invasion correlated with the presence of intrahepatic satellite metastasis ($P < 0·005$, χ^2 test).

Survival

Median follow-up for the entire cohort was 27 (4–117) months. Median survival was 59 months with a projected 5-year survival of 42 per cent (*Fig. 1*). Patients with stage II disease ($n = 16$) did significantly better (median survival 63 months) than patients with stage III tumours ($n = 15$; median survival 20 months) ($P < 0·02$). All four patients with positive nodal disease died; one from perioperative complications and the remaining three from recurrence at 6, 8 and 19 months. Vascular invasion and intrahepatic satellite lesions were predictors of worse survival ($P < 0·05$). Patients with positive resection margins ($n = 6$) had a worse median survival (9 months) than those with negative margins (63 months). Sex, age, perineural invasion and tumour site did not correlate with outcome.

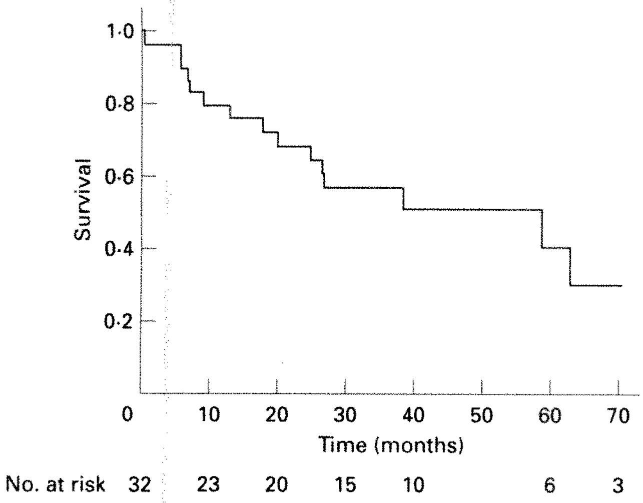

Fig. 1 Overall survival for patients undergoing resection for peripheral intrahepatic cholangiocarcinoma. Median survival was 59 months

Discussion

PIC is a relatively rare primary hepatic tumour, which is clinically distinct from hepatocellular carcinoma and extrahepatic cholangiocarcinoma. The majority of patients with hepatocellular carcinoma present with cirrhosis and raised serum AFP levels, whereas patients with perihilar or distal cholangiocarcinomas present with jaundice. In contrast, patients with PIC usually present with abdominal pain in the absence of jaundice, associated with a non-cirrhotic liver and normal serum AFP and CEA levels.

Similar to other Western reports[5], this series did not identify any risk factors associated with PIC. This is different from Asian series, which report an association with liver fluke infestation and hepatolithiasis[6–8]. This report also demonstrates that resection can be performed safely with an operative mortality rate of 3 per cent (one of 32 patients). This is similar to this institution's perioperative mortality rate for hepatic resection for non-cirrhotic hepatocellular carcinomas and metastatic tumours[9].

The overall median survival of 59 months for this series is significantly longer than that in other reported studies[3,5,8,10,11]. This improved survival is likely to be the result of patient selection. Patients with major bile duct involvement were excluded to ensure that patients with hilar cholangiocarcinomas were not included in this study. Some series include these patients, which might account for a worse survival rate[5,10,12]. The improved outcome in the present series may be explained by the early stage distribution; approximately half of the patients presented with stage II disease (node negative, no vascular invasion) and, in contrast to other reports[3,5], no patients with stage IVa disease in this cohort were resected. This early stage distribution most likely represents a combination of referral bias, as well as a selection bias by the surgeon.

In addition to stage, the presence of intrahepatic satellite lesions or vascular invasion predicted a worse outcome in this study. Interestingly, there was a significant correlation between microscopic vascular invasion and the presence of intrahepatic satellite metastasis. This association has also been described by others and has been suggested to be a factor contributing to the high incidence of early intrahepatic and extrahepatic metastasis associated with PIC[13]. Yamamoto *et al.*[12] reported that 60 per cent of resected PICs had evidence of vascular involvement and, of these, 83 per cent had intrahepatic metastasis; of the remaining lesions without vascular invasion, none had intrahepatic satellites.

The ability to obtain clear surgical margins also affected outcome. Six of the present patients had microscopically positive surgical margins, which translated into a worse median survival (9 months) compared with that of those with negative margins (63 months). Other series reported 26–36 per cent margin positivity rates[7,10], which also correlated with survival. This high rate of margin positivity may be explained by the fact that many patients present late, with large tumours often involving both lobes (eight of 32 in this series). In addition, 13 of 32 tumours demonstrated multicentricity. In an attempt to perform a more encompassing resection, many groups have reported hepatic transplantation for PIC. Results so far have been disappointing, and many centres now consider PIC a contraindication for transplantation[3,14].

The presence of hilar lymph node metastasis is associated with a worse survival. Only four patients had documented positive lymph nodes, all of whom died from either postoperative complications ($n = 1$) or recurrent tumour ($n = 3$). The poor prognosis of patients with lymph node metastasis has been documented by others. Chou *et al.*[7] reported a 0 per cent 1-year survival of patients with positive lymph nodes resected for PIC ($n = 11$). This was significantly worse than that for those with negative lymph nodes ($n = 8$), with a 3-year survival of 64 per cent. Pichlmayr *et al.*[3] also noted a worse survival for patients with node-positive disease who had a median survival of 7·7 months compared with 21·2 months for patients with node-negative tumours.

In summary, the results of surgical resection for PIC at a single tertiary care cancer centre are reported. PIC is usually associated with non-cirrhotic livers in the face of normal serum AFP and CEA levels. In selected patients, complete surgical resection can be performed safely and is associated with long-term survival. Stage, margin status, microvascular invasion and the presence of intrahepatic satellite lesions predict outcome. Data from other institutions provide discouraging results of hepatic transplantation for these patients, and the only curative option at the present time is complete surgical resection.

Background In adhesive small bowel obstruction, the early recognition of complications such as strangulation or volvulus is essential to choose between surgical or conservative initial treatment. The objective of this study was to determine prospectively the contribution of computed tomography (CT) to decision making in the management of these patients.

Methods Patients with suspected adhesive small bowel obstruction had CT at admission. Patients with CT signs of volvulus or strangulation and/or clinical signs of peritoneal irritation underwent urgent surgery; other patients had conservative initial treatment.

Results Fifty-four patients were evaluated. CT demonstrated signs of strangulation or volvulus in 19 patients, including three with signs of peritoneal irritation. Within this group, urgent laparotomy was performed in 17 patients and confirmed the CT diagnosis in 16. Thirty-seven patients without clinical or CT signs of complications had initial conservative treatment; among them, seven of 12 with a distal obstruction determined by CT required a delayed operation for persisting obstruction, compared with two of 25 patients with a proximal obstruction ($P < 0.01$).

Conclusion CT is useful for the evaluation of adhesive small bowel obstruction, to detect accurately patients with complications who require urgent operation and to determine the location of the adhesion, which represents a significant prognostic factor for success of conservative treatment

Conflicting opinions still exist about the choice between non-operative or surgical initial treatment for patients with adhesive small bowel obstruction (ASBO). This controversy is mainly related to the inability to differentiate accurately at an early stage strangulation from simple obstruction using conventional clinical criteria, plain abdominal radiography or laboratory data[1–4]. While successful conservative treatment has been reported[3,5,6], many authors recommend systematic early surgical exploration for all patients with ASBO to avoid excessive morbidity and mortality that may result from delayed operation[1,2,7].

Computed tomography (CT) has been advocated recently as a valuable procedure to evaluate ASBO. CT is able to diagnose the obstruction, its cause and location, and also to detect early signs of strangulation[8–13]. Moreover, CT may demonstrate the presence of volvulus secondary to adhesions, a condition that often leads to intestinal ischaemia or infarction[9,14,15].

The aim of the present study was to evaluate prospectively the contribution of CT to decision making in the management of patients with ASBO, first to detect at early stages the patients with complications, strangulation or volvulus, who have to be operated on as an emergency, and second to identify factors that may predict the success or failure of conservative treatment in patients with simple obstruction.

Patients and methods

From January 1995 to June 1997, all patients who presented with clinical symptoms of intestinal obstruction were candidates for inclusion in the study. Patients with an obstruction occurring in the month following an abdominal operation were excluded. Clinical evaluation consisted of physical examination, plain abdominal radiography and blood tests. As reported previously[1], the diagnosis of a strangulated occlusion was suggested clinically only by the presence of signs of peritoneal irritation. In contrast to partial obstruction, the diagnosis of complete obstruction was made at admission in cases of total constipation and when gas was absent in the colon on a plain abdominal radiograph.

All the patients had CT at admission, using a modern CT unit (Somatom Plus 4 A or C; Siemens Medical System, Erlangen, Germany); CT findings were interpreted independently from clinical data. On CT, the obstruction was demonstrated by the presence of dilated small bowel proximal to a transition zone and a collapsed distal small intestine or ascending colon. The diagnosis of ASBO was retained when no cause of obstruction could be identified at the level of the transition zone. The location of the obstruction, proximal or distal, was determined by the site of the transition zone. Based on the authors' experience and previous reports in the literature[10–13], the CT signs evaluated for the diagnosis of strangulation were: presence of ascites, presence of mesenteric congestion or intramesenteric fluid, wall thickening (bowel wall greater than 2 mm) and reduced mural enhancement after intravenous injection of contrast. This last sign was demonstrated by asymmetric enhancement in similarly distended adjacent loops, decreased in strangulated compared with non-strangulated bowel (*Fig. 1*). CT suggested the diagnosis of strangulation when reduced mural enhancement was demonstrated or when at least two of the other severity signs evaluated (ascites, mesenteric congestion, intramesenteric fluid or wall thickening) were present. Volvulus was diagnosed on CT if one of two signs was present: the whirl sign[16], corresponding to a whirlpool arrangement of the mesentery around the point of bowel torsion, and the abnormal distribution of the intestine with a fixed radial disposition of dilated bowel loops converging toward the point of torsion[14] (*Fig. 2*).

Presented in part to the Seventh European Congress of Surgery, Eurosurgery 97, Athens, Greece, 3–7 June 1997
Paper accepted 23 February 1998

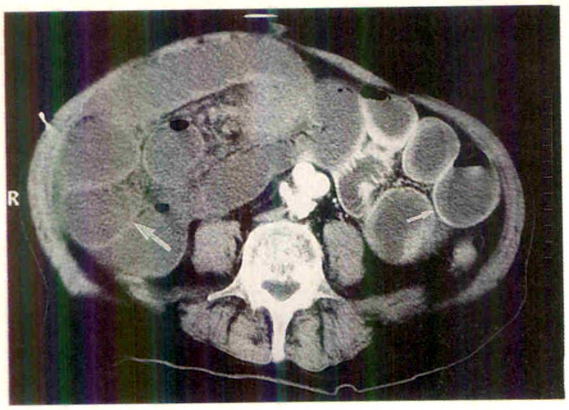

Fig. 1 Computed tomography after contrast injection, in a patient without signs of peritoneal irritation at admission, showed reduced mural enhancement (large arrow) in strangulated bowel loops compared with normal enhancement in similarly distended non-strangulated bowel (small arrow). Bowel ischaemia was confirmed at laparotomy and an intestinal resection of 180 cm was performed

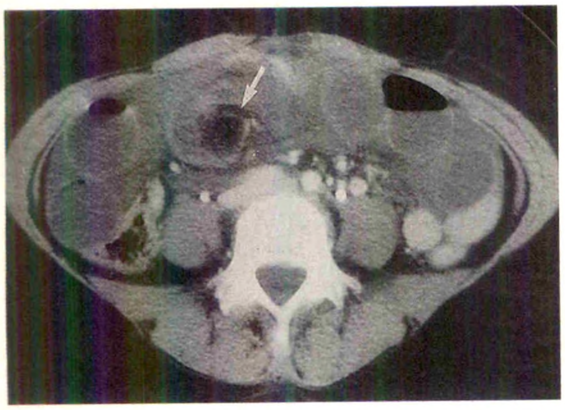

Fig. 2 Computed tomography at admission, in a patient without signs of peritoneal irritation, demonstrated a typical image of volvulus characterized by the presence of the whirl sign (arrow), consisting of a whirlpool arrangement of the mesentery around a central collapsed loop. Laparotomy confirmed the presence of a volvulus with secondary intestinal necrosis which required intestinal resection of 200 cm

After initial clinical and CT evaluation, all patients with a diagnosis of ASBO were included in the study. Two groups of patients were identified: patients with a suspicion of complicated obstruction, including those with clinical signs of peritoneal irritation and/or those with CT signs of strangulation or volvulus, and patients with a suspicion of simple ASBO with no clinical or CT signs of complication. Patients with suspected complicated ASBO underwent urgent laparotomy and those with a suspected simple obstruction were initially treated conservatively, using nasogastric decompression and administration of intravenous fluids. For patients treated conservatively, delayed laparotomy was decided upon when clinical conditions deteriorated or did not improve within 72 h. The final diagnosis was made at the end of the evaluation. The diagnosis of complicated obstruction was always established at laparotomy, when macroscopic signs of intestinal ischaemia and/or a volvulus of the bowel of at least 180° around the mesenteric vessels were observed. The diagnosis of simple ASBO was retained in patients relieved with non-operative therapy and in those whose operation did not reveal any ischaemic lesions or volvulus.

For each patient, initial clinical and CT findings were correlated with the final diagnosis. The efficacies of clinical judgement and CT were evaluated considering simple occlusion as negative and complicated occlusion as positive. According to this, the number of true-positive (TP), false-positive (FP), true-negative (TN) and false-negative (FN) diagnoses was determined. From these values, the sensitivity and specificity of clinical data and CT signs in the detection of complicated occlusion were calculated. Sensitivity was defined as the percentage of patients with complicated obstruction correctly detected ((TP/TP + FN) × 100). Specificity was defined as the percentage of patients with simple obstruction correctly diagnosed ((TN/TN + FP) × 100). Statistical analysis was with Fisher's exact test or Student's *t* test.

Results

Patients

Fifty-four patients were included in the study; there were 30 men and 24 women, ranging in age from 25 to 85 (mean 62) years. The previous laparotomy was for colorectal surgery in 16 cases, appendicectomy in ten, a gynaecological operation in nine, gastric surgery in seven and other procedure in 25, including biliary surgery, aortic replacement, urological operations, intestinal resection and kidney transplantation. Of the 54 patients evaluated, 34 (63 per cent) presented with a complete occlusion at admission.

Diagnosis

Sixteen patients had complicated obstruction confirmed at laparotomy. Three of these patients presented signs of peritoneal irritation at admission (*Table 1*). In these last three cases, the general condition of the patients allowed performance of abdominal CT before the operation. In all 16 patients with a final diagnosis of complicated obstruction, the CT findings suggested the presence of complications at admission (*Table 1*). In this group, 15 patients had CT signs of strangulation, associated with signs of volvulus in eight. Among these 15 patients, the CT diagnosis of strangulation was made on the basis of reduced mural enhancement in seven and was related to the demonstration of at least two of the other signs of severity in the other eight patients. The three patients with peritoneal signs showed mural enhancement on CT. One patient had CT signs of volvulus without associated signs of strangulation (*Table 2*).

Thirty-eight patients had a final diagnosis of simple occlusion; none of them presented peritoneal signs

Table 1 Comparative diagnostic value of clinical and computed tomographic signs for the diagnosis of complicated obstruction

	Complicated obstruction ($n = 16$)	Simple obstruction ($n = 38$)	Sensitivity (%)	Specificity (%)
Clinical diagnosis of complicated obstruction*	3	0	19	100
CT diagnosis of complicated obstruction†	16	3	100	92

*Clinical diagnosis of complicated obstruction was made in the presence of signs of peritoneal irritation; †computed tomographic (CT) diagnosis of complicated obstruction was made in the presence of signs of strangulation (reduced mural enhancement or at least two of the following signs: ascites, mesenteric venous congestion, intramesenteric fluid or mural thickening) or of volvulus (whirl signs and/or radial distribution of the mesentery)

Table 2 Value of computed tomography signs for the diagnosis of complicated obstruction

CT signs at admission	Complicated obstruction ($n = 16$)	Simple obstruction ($n = 38$)	Sensitivity (%)	Specificity (%)

Mesenteric congestion	10	5	62	87
Mesenteric fluid	10	0	62	100
Mural thickness	4	5	25	86
Whirl sign and/or radial distribution of the mesentery	9	1	56	97

CT, computed tomography

(*Table 1*). Of the three patients with CT findings that suggested complicated obstruction, one patient had CT signs of volvulus and was operated on as an emergency and two had CT signs of strangulation with the association of ascites and mesenteric venous congestion. Because of the good general condition of these last two patients and their immediate improvement after nasogastric aspiration, the surgeon judged that urgent operation was unnecessary and they received conservative initial treatment before the need for operation became clear. In seven patients with a final diagnosis of simple obstruction, isolated ascites was described on CT at admission.

Clinical outcome

All 16 patients with complicated obstruction were operated on. Intestinal resection for non-viability of the strangulated loop was performed in nine patients, including the three with clinical signs of peritoneal irritation; the remaining seven patients were treated with adhesiolysis only. Four complications were observed in this group including one case of respiratory insufficiency, one urinary infection, one wound infection and one case of septicaemia. One patient with a final diagnosis of simple obstruction was operated on as an emergency on the basis of a CT diagnosis of volvulus, which was not demonstrated at laparotomy. This patient was treated by simple adhesiolysis.

The remaining 37 patients with a simple obstruction were initially treated conservatively. Of these, 28 were relieved without operation, including the two patients with discrete CT signs of strangulation, and nine underwent delayed operation for persisting obstruction after a mean of 60 (range 24–120) h. In the group of nine patients who required delayed operation, intestinal resection for non-separable adhesions was performed in two and adhesiolysis in seven. Four complications were observed in patients with simple obstruction. One patient treated conservatively developed bacteraemia. Among the patients who underwent delayed operation, one with terminal hepatic failure died from multiple organ failure on the first day after a laparotomy performed 24 h after admission, one presented with a wound infection and one who had intestinal resection for non-separable adhesions developed secondary ischaemia of the distal bowel which required a second laparotomy for resection.

There was a significant association between distal location of the obstruction demonstrated on CT performed at admission and the failure of conservative treatment (*Table 3*). In the same patients, plain abdominal radiography performed at admission suggested that the obstruction was proximal in five patients and distal in four. In contrast to the location of the obstruction, the duration of symptoms before admission and the presence of partial or complete obstruction did not significantly affect the outcome after initial conservative management. There was no correlation between previous operative procedure and the evolution after conservative treatment.

Table 3 Evaluation of predictive factors for outcome after conservative initial treatment

	Successful conservative treatment ($n = 28$)	Delayed surgery ($n = 9$)	P
Mean(s.d.) duration of symptoms before admission (h)	49(39)	59(45)	n.s.†
Complete occlusion	16	3	n.s.‡
Distal location*	5	7	<0·01‡

*The location of the occlusion was determined by computed tomography at admission. n.s., Not significant. †Student's t test; ‡Fisher's exact test

Discussion

In cases of ASBO, the early distinction between simple and complicated obstruction, including strangulation and volvulus, is essential to select safely the patients for whom a trial of conservative treatment can be proposed and those who require urgent surgical exploration. Conservative initial treatment may allow a reduction in the number of unnecessary operations in patients with simple obstruction; in contrast, urgent surgery could reduce the morbidity and probably the rate of intestinal resection in patients with complicated obstruction.

As reported previously[1–4], clinical judgement, depending on the presence of signs of peritoneal irritation, was not reliable for early differentiation of simple and complicated obstruction in the present study. In contrast, on the basis of the criteria evaluated, CT was sensitive and specific for the detection of strangulation and volvulus, before the appearance of clinical symptoms.

Reduced mural enhancement was found to be a highly specific CT sign of strangulation but its sensitivity was less than 50 per cent. Similarly, intramesenteric fluid was a very specific but poorly sensitive sign in patients with strangulation; the validity of this particular sign, not previously mentioned, must be evaluated further in larger series. Signs of severity such as ascites or mesenteric congestion were sensitive for the detection of complicated obstruction but their isolated specificity remained limited. Ascites and mesenteric congestion were demonstrated in 12 and ten respectively of the 16 patients with complicated obstruction but also in seven and five of the 38 patients with simple obstruction. Similar observations concerning the presence of ascites in patients with simple obstruction have been described previously with the use of ultrasonography[17]. If the presence of at least two of these severity signs, including ascites, mesenteric congestion, intramesenteric fluid or mural thickening, was required for the diagnosis of strangulation, their combined specificity exceeded 90 per cent.

Independently of the signs of strangulation, volvulus was diagnosed on CT at admission in nearly 20 per cent of the patients evaluated and in nine of the 16 patients with complicated obstruction. The presence of a volvulus was confirmed at laparotomy in all cases but one. Among the patients with a volvulus proven at laparotomy, most had intestinal ischaemia of the twisted loop and four required a resection for non-viability. This observation, in agreement with previous reports[15,18], emphasizes the major pathogenic role of volvulus in ASBO and underlines the need for early surgical treatment of this condition.

Demonstration of the signs of strangulation or volvulus led to CT diagnosis of complicated obstruction with an overall sensitivity of 100 per cent and a specificity superior to 90 per cent. On this basis, CT has a major impact on the early management decision in the authors' experience; in all the patients with complicated obstruction, CT findings prompted urgent laparotomy although this approach was suggested by signs of peritoneal irritation in only three of 16 patients.

When CT signs of severity are isolated or limited, their exact significance has still to be defined. Moreover, CT signs of strangulation indicated by the association of ascites and mesenteric congestion were observed in some patients with a final diagnosis of simple obstruction. Despite initial conservative treatment, none of these patients developed complicated obstruction during follow-up. This could be related either to the non-specificity of these signs or to the reversibility of early ischaemic lesions if they are treated with nasogastric aspiration.

In the management of ASBO, a second question of interest is to differentiate, in patients with a simple obstruction, those who will be relieved with conservative treatment from those who will require operation for persisting obstruction. Accurate location of the obstruction on CT may represent a valuable predictive factor. Patients developing ASBO after appendicectomy or operation on the ovary or tube more frequently require surgical treatment[19]. In these cases, the presence of band adhesions in the pelvis is likely to cause distal obstruction. In the present series, however, the occurrence of persisting obstruction after initial conservative treatment was not related to the type of previous surgery.

In conclusion, these results suggest that CT could play a key role as a first diagnostic procedure in the management of patients with ASBO. In this condition, CT is able accurately to define three categories of patients and specifically direct management in each of these groups: first, patients with strangulation or volvulus that requires urgent surgical treatment; second, patients with a proximal simple obstruction who most probably will be relieved with conservative treatment; and, finally, patients with a simple distal obstruction who will require operation for a persisting occlusion in more than 50 per cent of cases. For these last patients, the ideal treatment has still to be defined; it has been suggested that a semiurgent laparoscopic division of adhesions may be a suitable form of management[19,20].

Geographical inequality in the provision of carotid endarterectomy in Scotland

D. J. ADAM, M. BAIN*, E. SHANKS* and A. W. BRADBURY on behalf of the Scottish Vascular Audit Group

*Vascular Surgery Unit, University Department of Surgery, Royal Infirmary and *Information and Statistics Division of the National Health Service in Scotland, Edinburgh, UK*

Correspondence to: Mr D. J. Adam, Vascular Surgery Unit, University Department of Surgery, Royal Infirmary, Edinburgh EH3 9YW, UK

Background Carotid endarterectomy (CEA) is a proven method of stroke prevention in patients with symptomatic and asymptomatic high-grade internal carotid artery stenosis. This study examined whether site of residence affects access to CEA in Scotland.

Methods Scottish Morbidity Record hospital discharge data were collected by the Information and Statistics Division of the National Health Service in Scotland and analysed for the interval 1 January 1989 to 31 December 1995. The number of CEAs performed in the hospitals of each of the 15 regional Health Boards, and CEA rate per 100 000 population resident in each Health Board region, were determined.

Results In 1989, 65 CEAs were performed in the hospitals of five Health Boards and in 1995, 431 CEAs were performed in nine Health Boards. In 1989, the CEA rate per 100 000 resident population varied between 0 (four regions) and 4 (one region), with one region significantly different from Scotland as a whole ($P < 0{\cdot}01$). In 1995, the CEA rate varied between 0 (two regions) and 19 (one region), with two regions significantly different from Scotland as a whole ($P < 0{\cdot}01$).

Conclusion Despite a sixfold increase in the number of CEAs being performed, and a rise in the number of centres performing CEA, there is increasing geographical inequality in the provision of CEA in Scotland.

Two, large multicentre randomized controlled trials have indicated that, in patients with symptomatic internal carotid artery stenosis equal to or exceeding 70 per cent, carotid endarterectomy (CEA) in addition to best medical therapy is associated with a significant reduction in the rate of future stroke compared with best medical therapy alone[1,2]. Although estimates vary widely, the Association of British Neurologists has assessed the incidence of symptomatic carotid artery stenosis to be 43 per 100 000 per year and have suggested that nine patients per 100 000 per year might be candidates for CEA[3]. The Asymptomatic Carotid Atherosclerosis Study (ACAS) has recently shown that CEA, in addition to best medical therapy, does significantly reduce stroke risk in patients with asymptomatic internal carotid artery stenosis equal to or exceeding 60 per cent[4], the incidence of which is estimated to be 800 per 100 000 per year[5]. These data have far reaching implications for the future allocation of resources and personnel to CEA. The aim of this study was to examine whether site of residence in Scotland affects patient access to CEA.

Patients and methods

The National Health Service (NHS) in Scotland comprises 15 regional Health Boards (*Fig. 1*). The Information and Statistics Division (ISD) of the NHS in Scotland collects information on all hospital discharges through the Scottish Morbidity Record 1 (SMR 1). The accuracy of SMR 1 clinical data for main operation is between 85 and 91 per cent, and for main diagnosis approximately 89 per cent[6]. With regard to CEA, the Quality Assessment and Accreditation Unit of the ISD compared SMR 1 data and surgeons' own audit data in 33 hospitals throughout Scotland, and discovered 100 per cent concordance. Between 1 January 1989 and 31 December 1995 (the last year for which complete data are available), the following were obtained for each of the 15 regional Health Boards: the number of individuals resident in each region who were discharged from hospital with a diagnosis of stroke of any aetiology (International Classification of Diseases, ninth revision (ICD-9) codes 430–434, 436, 437); the number of individuals resident in each region who were discharged from hospital with a diagnosis of transient ischaemic attack (TIA) (ICD-9 code 435); the number of individuals resident in each region who died, both in hospital and out of hospital, as a consequence of stroke (all causes); the number of CEAs performed in NHS hospitals in Scotland (Office of Population Census and Surveys (OPCS4) codes L29.4, L29.5); and the number of CEAs performed on the residents of each region. Population estimates from the Registrar General for Scotland were used to calculate the following for each Health Board area: stroke (all causes) incidence and stroke mortality rate per 100 000 resident population; TIA incidence per 100 000 resident population; and the CEA rate per 100 000 resident population.

The Bonferroni method was used to make comparisons between rates in individual Health Boards and Scotland as a whole; a probability value of less than 0·01 was regarded as statistically significant (99 per cent confidence interval, adjusting for the number of tests). The Mann–Whitney U test was used to compare population demographics; $P < 0{\cdot}05$ was regarded as statistically significant (95 per cent confidence interval).

Results

A significantly greater proportion of the population of 14 of the 15 Health Boards was aged 45–64 years in 1995 (median 24 (range 21–25) per cent) compared with 1989

Paper accepted 20 December 1997

(median 22 (range 19–24) per cent) ($P<0{\cdot}01$). There was, however, no significant difference in the proportion who were aged 65 years or older (median 16 (range 13–19) per cent) in 1995 *versus* median 15 (range 13–28) per cent in 1989; $P=0{\cdot}65$).

During the 7-year study interval, the annual incidence of hospitalized stroke (all causes), death from stroke and hospitalized TIA varied considerably between Health Boards (*Figs 2–4*) and bore no relationship to the number of CEAs performed (*Fig.* 5). In 1989, the CEA rate per 100 000 resident population ranged between zero in four regions (Highland, Orkney, Shetland and Western Isles) and 4·1 in Tayside, where the rate was significantly higher than in any other region ($P<0{\cdot}01$). In 1995, the CEA rate ranged from zero in two regions (Orkney and Shetland) to 19·0 in Tayside. The operation rates in Ayrshire and Arran (16·7) and Tayside (19·0) were significantly higher than in the other regions ($P<0{\cdot}01$) (*Fig.* 5). The CEA rate in Scotland per 100 000 resident population was 1·3 in 1989 and 8·4 in 1995.

A total of 1731 CEAs were performed between 1989 and 1995. The median age of patients was 63 (range 36–89) years. In 1989, 65 operations were performed in five of 15 Health Board regions whereas in 1995, 431 procedures were performed in nine Health Boards. Seventy-eight per cent of CEAs (1355) were performed in three Health Board areas (Greater Glasgow, Lothian and Tayside). Two centres collaborated in CEA trials. In Lothian, CEA was performed in nine of 17 patients randomized in the Carotid and Vertebral Artery Transluminal Angioplasty Study (CAVATAS) and six of 12 randomized in the Asymptomatic Carotid Surgery Trial (ACST). In Tayside, CEA was performed in 14 of 27 patients randomized in the ACST.

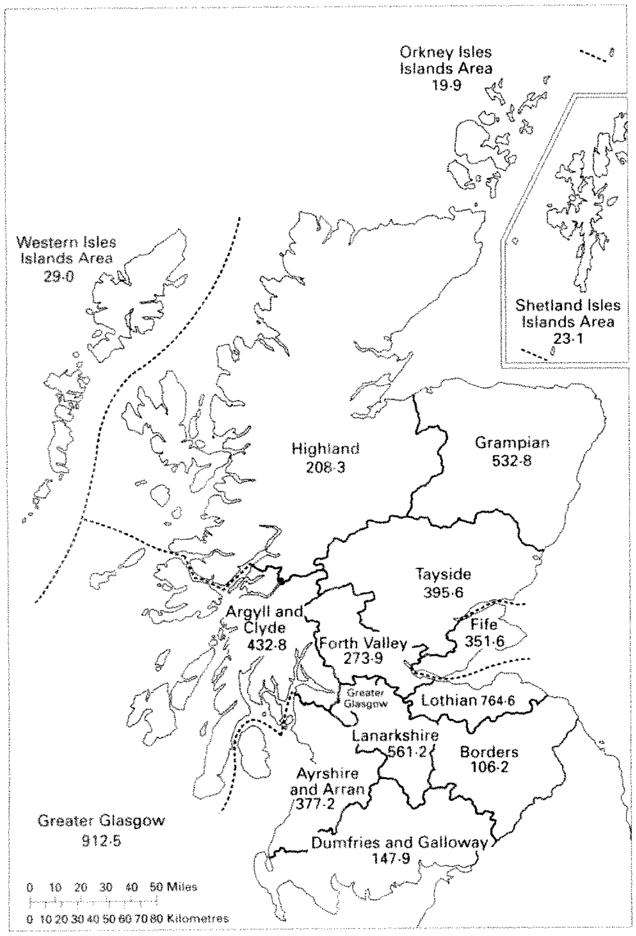

Fig. 1 Population (in thousands at 30 June 1995) and area boundaries (------) of the 15 regional Health Boards in the National Health Service in Scotland

Discussion

There has been a sixfold increase in the number of CEAs performed in Scotland between 1989 and 1995, most of which has occurred since publication of the two large multicentre randomized controlled trials. The CEA rate in Scotland in 1995 was over two and a half times that for the rest of the UK in 1993 (8·5 *versus* 3·3 per 100 000)[7], but less than one-quarter of that in the USA in 1993 (36 per 100 000)[8]. Although it would appear that the CEA rate in Scotland is approaching the level suggested by the Association of British Neurologists[3], there are wide variations in the number of residents in each Health Board region undergoing CEA.

In the present study, no information was available on the indication for surgery, although a guideline produced by the Scottish Vascular Audit Group, of which all Scottish vascular surgeons are members, recommends CEA for symptomatic disease only with stenosis greater than 70 per cent, and for asymptomatic disease only within the context of a clinical trial. Data regarding CEA performed in non-NHS hospitals were not available, but are likely to include a small number of patients.

Despite an overall increase in the number of CEAs performed, and an increase in the number of centres undertaking carotid surgery, there is increasing geographical inequality in the provision of CEA. Such variation in CEA provision has been observed in the USA[9].

Can the differences in CEA provision be explained by differences in stroke and TIA rates between Health Boards? As only a proportion of strokes are due to carotid artery stenosis, and CEA is aimed at preventing and not treating stroke, this question could only be answered definitively by examining Health Board differences in the incidence of carotid territory TIA. Unfortunately, the true incidence of TIA is not known as many patients do not report symptoms, and only a proportion of those who attend their general practitioner are referred to hospital[10].

In the present study, there is no suggestion that the utilization of CEA as a means of stroke prevention is related to the incidence of hospitalized stroke, death from stroke or hospitalized TIA in any particular region, or to differences in patient demography. It is likely that the differences between Health Boards are due to variations in referral practice. Whether it is general practitioners who do not refer a patient to a hospital specialist, or non-surgical specialists who fail to refer patients from regions where a vascular surgeon who performs CEA is not available, remains unknown. The present study clearly indicates that, even in Scotland where the overall CEA rate is the highest in the UK, patients in certain regions may have significantly reduced access to CEA.

Background L-Arginine-depleted environments accompanying ischaemia–reperfusion enhance superoxide production, leading to the formation of reactive oxygen species and a concomitant reduction in basal nitric oxide levels. The bioflavonoid quercetin may prevent these undesirable effects by scavenging superoxide.

Methods Untreated rabbits were compared with those infused with quercetin (5 mg/kg for 2 min) during hindlimb ischaemia (2·5 h) and reperfusion (2 h). In both groups, nitric oxide concentration was measured (porphyrinic microsensor) in the femoral artery wall. Microvasculature changes (morphometry) and superoxide concentration (chemiluminescence) were measured intermittently in biopsies.

Results Approximately 6 min into the period of ischaemia a rapid increase in nitric oxide level from a mean(s.e.m.) basal level of 50(20) to 450(30) nmol/l was observed. In untreated animals, nitric oxide concentration dropped to an undetectable level (less than 1 nmol/l) during reperfusion. In quercetin-treated animals, the decrease in nitric oxide concentration was slower, such that substantial amounts (60(20) nmol/l) accumulated during reperfusion. In biopsies after ischaemia–reperfusion maximal calcium ionophore A23187-stimulated nitric oxide concentration increased (25-30 per cent) in the presence of quercetin, while the superoxide concentration decreased.

Conclusion Quercetin treatment mollified ischaemia–reperfusion injury to skeletal muscle by scavenging destructive superoxide and enhancing the cytoprotective nitric oxide concentration.

Increased production of reactive oxygen species during ischaemia–reperfusion injury leads to a consumption and depletion of endogenous scavenging antioxidants[1]. The consequences of such injury, frequently observed in surgical patients, are local and remote tissue destruction, and sometimes the death of the patient[2,3].

Acting on encouraging epidemiological studies[4] suggesting a possible protective role of moderate alcohol intake (in particular red wine) on the incidence of coronary heart disease ('the French paradox'), Fitzpatrick *et al.*[5] recently investigated the effects of various components of grapes on rat aortic rings. Among the major components of red grape skin, they found that quercetin (a low molecular weight bioflavonoid) relaxed rat aortic rings (precontracted with phenylephrine) while it significantly increased the intracellular concentration of guanosine 3′, 5′-cyclic monophosphate, the product of nitric oxide-agonized enzyme. These quercetin-induced effects were obliterated by denuding the constitutive nitric oxide synthase (cNOS)-studded endothelium, or by incubation with inhibitors of cNOS. Therefore, it was suspected that quercetin might interact with endothelial cNOS, or its products.

Under normal conditions in mammalian tissue, cNOS receives and stores enough electrons from reduced nicotinamide adenine dinucleotide phosphate (NADPH) to transform its substrates oxygen and L-arginine into its products L-citrulline, nitric oxide and water[6]. Under abnormal conditions, in L-arginine or (6R)-5,6,7,8-tetrahydrobiopterin (H_4B)-depleted environments, it has been demonstrated *in vitro* that at least one cNOS isoform can still receive electrons from NADPH and, when activated, donate them to its substrate oxygen alone, resulting in the formation of superoxide[7]. Living mammals, freshly excised tissue, or even tissue cultures naturally contain a large concentration of superoxide dismutase (SOD; 5–10 μmol/l) that rapidly converts superoxide into hydrogen peroxide[8], and a similarly large concentration of catalase that converts hydrogen peroxide into water and oxygen at a more moderate rate[8]. Nitric oxide and hydrogen peroxide are potent vasodilators[9,10], and superoxide is a potent vasoconstrictor[11]. However, the product of the rapid ($k = 6{\cdot}7 \times 10^9$ litres per mol per s)[12] reaction of nitric oxide with superoxide, peroxynitrite, is a relatively impotent vasodilator[13].

Since the amount of SOD in tissue cannot effectively prevent the non-enzymatic reaction of nitric oxide with superoxide as long as basal concentrations of nitric oxide are maintained, at least two major strategies may possibly prevent excess superoxide production and subsequent ischaemia–reperfusion injury. The first is based on treatment with H_4B, L-arginine or their analogues, thus preventing L-arginine- and H_4B-deficient conditions so cNOS will not produce excessive superoxide[14]. The second is based on scavenging superoxide already produced by cNOS and other potential sources of superoxide by using SOD and other free radical scavengers[15]. This paper describes the use of the second strategy, and tested the hypothesis that pretreatment with quercetin would mollify

ischaemia–reperfusion injury by affecting the superoxide and nitric oxide production. In these experiments continuous *in vivo* measurement of nitric oxide production was correlated with intermittent measurement of superoxide production. Microvasculature changes (microvessel cross-sectional area alterations) were measured morphometrically as an indicator of ischaemia–reperfusion injury.

Materials and methods

Animal preparation for in vivo *studies*

The *in vivo* studies were performed on adult male New Zealand white rabbits (Charles River, Sulzfeld, Germany) according to the 'Guiding Principles in the Care and Use of Animals'. The rabbits had free access to food (Altromin 2120 standard diet pellets; Marek, Vienna, Austria) and water.

Rabbits anaesthetized using a mixture of ketamine hydrochloride 15 mg/kg and xylazine hydrochloride 1·5 mg/kg were intubated and ventilated with nitrous oxide–oxygen and isoflurane (concentration 1–2 vol per cent). Ventilator parameters were adjusted according to blood gas values to achieve the normal range of partial pressures of oxygen and carbon dioxide, and pH and oxygen saturation in arterial blood samples obtained from the carotid artery. Blood arterial pressure was monitored in the carotid artery (physiological pressure transducer; Berg, Kirchseeon/Eglharting, Germany). Blood flow was measured with the Transonic System (Model T 106, Ithaca, USA).

Bilateral hindlimb ischaemia was achieved according to an established technique[16]. Blood flow occlusion as well as reperfusion were confirmed with a blood perfusion monitor (Laserflo BPM2; Vasamedics, St Paul, Minnesota, USA). The hindlimb ischaemia time was 2·5 h followed by 2 h of reperfusion. Animals ($n = 7$) were treated by intravenous infusion into the auricular vein of a water-soluble form of quercetin (5 mg/kg over 2 min). Ischaemia was started 40 min after quercetin infusion. The animals subjected to ischaemia–reperfusion but without quercetin treatment received a placebo infusion of 0·9 per cent saline and served as controls ($n = 7$).

Preparation of nitric oxide sensors for in vitro *and* in vivo *measurements*

Preparation of the catheter-protected porphyrinic sensor[17–19] was slightly different from that previously described[20]. Specifically, the needle shaft was truncated 3 mm shorter, instead of 0·5 mm longer, than its protective catheter. Using a 24-G placement needle (clad with its catheter with two 50-μm ventilation holes near the tip), femoral artery smooth muscle tissue was pierced, then the needle was advanced to the desired place in the vessel wall. The position of the catheter was secured, and the placement needle was removed and replaced by a 24-G porphyrinic nitric oxide sensor.

For positioning the flexible active tip of the porphyrinic sensor on a microvessel, a lower limb of a rabbit was positioned under a dissecting microscope. Surgical microdissection was performed until a microvessel (mean(s.e.m.) (50) μm) was visualized. Then, a porphyrinic sensor was lowered with the help of a stereotactic micromanipulator until the surface of the observed blood vessel was reached. A platinum wire counterelectrode and a reference silver/silver chloride electrode were placed in contact with adjacent tissue.

Differential pulse voltammetry (DPV) or chronoamperometry was performed using a PAR model 273 voltammetric analyser (potentiostat plus waveform generator; EGG Princeton Applied Research, Oak Ridge, USA) interfaced with an IBM 80 486 computer (Gateway, North Sioux City, USA) with data acquisition and control software. DPV was used to measure the basal nitric oxide concentration. Chronoamperometry was used for fast (resolution time 0·1–1 ms) and continuous measurement of the changes in nitric oxide concentration from basal level with time. Linear calibration curves were constructed for each sensor from 2×10^{-9} to 2×10^{-5} mol per litre nitric oxide, before and after measurements, with aliquots of saturated nitric oxide prepared as described previously[21].

Indirect and direct superoxide measurement

To determine the superoxide concentration in freshly excised tissue indirectly nitric oxide release was stimulated with a calcium ionophore (A23187, 10 μmol/l), and the nitric oxide concentration was measured in the presence and absence of SOD 100 units ml as described above. The difference in concentrations was assumed to be equal to the superoxide concentration.

To confirm the indirect method, the superoxide concentration was determined directly by a chemiluminescence method in fresh biopsies[22]. Superoxide produced chemiluminescence of lucigenin (bis-*N*-methylacridinium nitrate; Aldrich Chemical Company, Milwaukee, Wisconsin, USA), which was detected with a scintillation counter (Beckman 6000LS, with a single photon monitor; Beckman, Fullerton, USA). Each tissue sample (8–15 mg) was placed in 2 ml Hanks' Balanced Salt Solution (HBSS; Sigma Chemical Company, St Louis, Missouri, USA) adjusted to pH 7·4 at 25°C, then enough lucigenin was added to give a concentration of 0·25 mmol/l. Basal superoxide concentration produced by the tissue was measured after a 2-min incubation in HBSS. The sum of the superoxide produced by the L-arginine- or H_4B-depleted cNOS and other sources (stimulated) was measured in a similar manner, except the 2-min incubation period was followed by injection of 20 μl of A23187 1 mmol/l (a receptor-independent cNOS agonist). Photon counts were calibrated by constructing standard curves of superoxide concentration generated stoichiometrically by treating xanthine with xanthine oxidase.

Morphological investigations

Adductor magnus muscle tissue samples were removed from the hindlimb before the onset of ischaemia, at the end of ischaemia and 2 h after reperfusion. Tissue samples were immediately immersed for quick freezing at −70°C in a 2-methylbutane solution (Uvasol; Merck, Darmstadt, Germany) for 2 min. The samples were stored at −80°C until they were sectioned. Transverse cryosections of 10 μm thickness (Kryostat 1720; Leitz, Germany) were stained for actomyosin adenosine 5′-triphosphatase (ATPase) activity at pH 4·3 and were examined by light microscopy (Axiomat; Zeiss, Oberkochen, Germany). Capillaries were measured with a pen linked to a personal computer using a semiautomatic image-analysing system (LUCIA M; Nikon Laboratory Imaging, Prague, Czech Republic) at a 1000-fold magnification. Fifty microvessels per random field were measured in each section, and the microvessel cross-sectional area was determined. After completion of the experimental investigation, the animals were killed by intravenous administration of an overdose of potassium chloride.

Statistical analysis

Data are expressed as mean(s.e.m.). Statistical analysis was by unpaired Student's *t* test or by analysis of variance followed by Schette's test. Means were considered statistically different at $P < 0·05$.

Results

A typical chronoamperometry curve (current calibrated as nitric oxide concentration *versus* time) was obtained from *in situ* measurement of nitric oxide in a freshly excised rabbit aorta (*Fig. 1a*). Immediately after administration of a receptor-independent cNOS stimulator, A23187 10 μmol/l, an initial rapid increase in nitric oxide concentration was observed. The peak concentration of nitric oxide was 310(30) nmol/l. This peak concentration increased to 420(35) nmol/l after A23187 stimulation of nitric oxide in the presence of quercetin 4 µmol/l. A similar increase in nitric oxide concentration was observed in the presence of SOD 100 units/ml (*Fig. 1b*); nitric oxide peak concentration increased from 300(30) to 405(20) nmol/l.

It was hypothesized that quercetin is a rapid scavenger of superoxide like SOD and either compound was used in the indirect estimation of superoxide production at the time of nitric oxide release. Nitric oxide concentration enhancement (by rapid superoxide scavenging by quercetin) increased as the concentration of quercetin increased up to 30 µmol/l (*Fig. 2*). At quercetin concentrations higher than 30 µmol/l a rapid decline in the beneficial effect on production of nitric oxide was observed. That quercetin was scavenging superoxide was substantiated by the use of a chemiluminescence method to make direct *in vitro* measurements of superoxide concentration in freshly excised aorta. The basal concentration of superoxide in the tissue (before A23187 stimulation of cNOS) was 12(3) nmol per litre per mg tissue ($n = 7$); it decreased to 6(1) nmol per litre per mg tissue in the presence of quercetin (*Fig. 3*). After A23187 stimulation, superoxide concentration increased to 27(3) nmol per litre per mg tissue in the absence of quercetin. However, in the presence of quercetin 10 µmol/l the superoxide concentration decreased to 7(1) nmol per litre per mg. This is significantly lower than in the absence of quercetin ($n = 7$, $P < 0{\cdot}005$) (*Fig. 3*).

A typical chronoamperometry curve was obtained from the *in vivo* measurement of nitric oxide concentration with the sensor placed in the wall of the femoral artery. Administration of quercetin (5 mg/kg over 2 min), without subsequent femoral artery clamping, caused an increase in nitric oxide concentration to 110(20) nmol/l ($n = 7$) above its basal level (*Fig. 4*). The increase in nitric oxide concentration was accompanied by a decrease in blood pressure of 20 mmHg (*Fig. 4*).

A nitric oxide sensor placed in the wall of the femoral artery *in vivo* showed an increase in nitric oxide production shortly (340(30) s) after the femoral artery was clamped (*Fig. 5a*). The concentration of nitric oxide reached a peak (450(30) nmol/l) and after that dramatically decreased with time (40 min) below its original basal concentration (50(20) nmol/l). Treatment with quercetin was quickly followed by an increase in nitric oxide concentration with a simultaneous decrease in blood pressure (*Fig. 5b*). After the femoral artery was clamped an initial burst of nitric oxide production (maximum 440(30) nmol/l) was observed, which later decreased gradually approximately to its basal level. During reper-

fusion, the nitric oxide concentration remained constant, and flow increased above its preischaemic level without a change in pressure.

Morphological changes

No significant changes in the size of microvessels in skeletal muscles of untreated animals were observed during the ischaemia period. However, 2 h after reperfusion, significant microvessel constriction was documented: the microvessel cross-sectional area decreased from $19{\cdot}15(0{\cdot}76)\,\mu m^2$ at the end of ischaemia to $12{\cdot}64(1{\cdot}15)\,\mu m^2$ after 2 h of reperfusion ($P < 0{\cdot}005$). In the muscles of quercetin-treated animals, no significant change in microvessel size was observed either at the end of ischaemia or 2 h after reperfusion.

Discussion

The model underlying these studies is that in the L-arginine-deficient environment accompanying ischaemia cNOS may initiate high production of superoxide and lead to rapid scavenging of nitric oxide to form peroxynitrite[14]. Although peroxynitrite is relatively stable, when protonated ($pK_a = 6{\cdot}8$), the rapidly formed peroxynitrous acid ($t_{1/2}$ less than 1 s) rearranges to form the relatively harmless hydrogen cation and nitrate anion[23]. However, any process that increases the local nitric oxide or superoxide concentration may cause the local peroxynitrous acid concentration to become sufficient enough to assure its efficient transport to reactive sites as far as several cell diameters away[23]. In the vicinity of certain reactive centres, peroxynitrous acid may undergo homolytic cleavage to hydroxyl free radical and nitrogen dioxide free radical, or heterolytic cleavage to nitronium cation and hydroxide anion[14]. Three of these cleavage products (hydroxyl free radical, nitrogen dioxide free radical and nitronium cation) are among the most reactive and damaging species in biological systems, and may initiate a cascade of events leading to severe ischaemia–reperfusion damage[23].

As evident from the data obtained, quercetin may increase total nitric oxide concentration by scavenging superoxide. At the maximum effective concentration of $30\,\mu$mol/l, quercetin appears to be a more potent scavenger of superoxide than SOD 100 units/ml (approximately the normal physiological concentration of SOD)[8]. The apparently larger amount of superoxide scavenged by quercetin displayed in *Fig. 1a* is most likely the result of prolonged nitric oxide production by endothelial cNOS. Quercetin certainly scavenges superoxide[24], but it is also known as a protein kinase C inhibitor[25]. Endothelial cNOS is normally turned off by phosphorylation of one of its serine residues by a phosphate group provided by protein kinase C a minute or so after the endothelial cNOS is turned on[26]. It is suggested that quercetin is not only a good scavenger of superoxide but that it also prolongs the endothelial cNOS burst by inhibiting protein kinase C, the enzyme that provides the negative switch.

Furthermore, high concentrations of quercetin have been reported to inhibit the nitric oxide generating activity of endothelial cNOS ($IC_{50} = 220\,\mu$mol/l)[27]. It is evident from *Fig. 3* that quercetin also effectively inhibits the superoxide generating activity ($IC_{50} = 100\,\mu$mol/l). However, the exact cause(s) may be difficult to ascertain, since plant phenols display a multiplicity of other biochemical actions, such as inhibition of the sacroplasmic reticulum calcium ATPase in skeletal muscle, stimulation of cardiac sacroplasmic recticulum calcium ATPase, and inhibition of the sodium–potassium ATPase and phosphodiesterase, which complicate interpretation of the effects at the cell or tissue level[27].

B-dihydroxy flavones like quercetin produce hydrogen peroxide after scavenging superoxide[28]. *In vivo*, this is usually not a problem because there is sufficient catalase present to rapidly convert the hydrogen peroxide into water and oxygen[8]. However, the ubiquitous presence of free ferrous ion accompanying *in vitro* studies will rapidly convert hydrogen peroxide into hydroxyl free radical (Fenton reaction), the most destructive species in biological systems[28]. At least one *in vitro* study[28] reports that quercetin accelerates the production of hydroxyl free radicals in the presence of ferrous ion (most probably quercetin rapidly transforms the existing superoxide into hydrogen peroxide, then the Fenton reaction works rapidly). *In vivo* systems are protected from this disastrous reaction by the iron transporter, ferritin, which quickly scavenges any free ferrous ion.

In general, direct, but intermittent, chemiluminescent measurements of superoxide in freshly excised tissue during the course of ischaemia–reperfusion provide strong indications that superoxide can be produced in relatively high concentrations during ischaemia–reperfusion. Furthermore, this superoxide production is inversely related to nitric oxide accumulation continuously measured by the nitric oxide sensor. A dramatic decrease in nitric oxide concentration was observed during reperfusion when production of superoxide was the highest. Paralleling this low nitric oxide concentration during reperfusion, a significant decrease in the diameter of microvessels was observed[14].

Treatment with quercetin before ischaemia–reperfusion prevented significant accumulation of superoxide and helped to maintain the concentration of nitric oxide at its basal level during reperfusion. The physiological level of nitric oxide prevented microvessel constriction in reperfused muscle.

In conclusion, the present study demonstrates that quercetin may be useful in protecting skeletal muscle from ischaemia–reperfusion injury. Nitric oxide deficiency due to its consumption by superoxide produced at a high concentration during ischaemia–reperfusion plays an important role in the pathophysiology of ischaemia–reperfusion injury. Quercetin treatment prevents excessive accumulation of superoxide and preserves nitric oxide concentration at a level sufficient to maintain vasorelaxation in the surrounding smooth muscles, while inhibiting platelet aggregation and adhesion within the lumen.

Influence of ischaemia–reperfusion injury on CD44 expression in rat small intestine

K. HEEL, L. BLENNERHASSETT, S.-E. KONG, R. McCAULEY and J. HALL

University Department of Surgery, Royal Perth Hospital, Wellington Street, Perth, 6001 Western Australia, Australia
Correspondence to: Professor J. C. Hall

Background CD44 is an adhesion molecule expressed by neutrophils and lymphocytes which is involved in cell–cell and cell–matrix binding. In this study, the effect of ischaemia–reperfusion injury on CD44 messenger RNA (mRNA) and cell surface immunohistochemical expression of CD44 in the rat small intestine was evaluated.

Methods Wistar rats ($n = 16$) were randomized to either serve as controls (sham surgery) or to be subjected to a standardized ischaemia–reperfusion injury (suprarenal aorta occluded for 1 h followed by 1 h of reperfusion). Standardized segments of jejunum were harvested after ischaemia–reperfusion injury (ischaemic and reperfused samples) to measure the mucosal protein and DNA content, mRNA expression of CD44 and the immunohistochemical expression of CD44.

Results Reperfusion significantly damaged the jejunal mucosa, e.g. mucosal protein content was lower after reperfusion compared with that in the control group ($z = -2{\cdot}31$, $P = 0{\cdot}02$) and the ischaemic samples ($z = -2{\cdot}52$, $P = 0{\cdot}01$). The expression of cell surface CD44 protein was also significantly decreased after ischaemic injury ($z = -1{\cdot}99$, $P = 0{\cdot}04$); this coincided with a decrease in the amount of cytoplasmic CD44 mRNA within isolated enterocytes ($z = -2{\cdot}31$, $P = 0{\cdot}02$).

Conclusion Ischaemia–reperfusion injury decreases the expression of CD44 within the jejunal mucosa. This may contribute to the failure of the gut barrier after such injury.

The migration, accumulation and activation of polymorphonuclear neutrophils (PMNs) is a key event in ischaemia–reperfusion injury[1,2]. CD44 is a transmembrane glycoprotein expressed by neutrophils and lymphocytes which is involved in cell–cell and cell–matrix binding. Hence CD44 may play a key role in events such as PMN migration, lymphocyte homing and cancer metastasis[3–6]. In this study, the effect of ischaemia–reperfusion injury on CD44 messenger RNA (mRNA) and immunohistochemical expression of CD44 in the rat small intestine was evaluated.

Patients and methods

Sixteen male Wistar rats (300–350 g) were allowed 1 week to acclimatize before surgery. The rats were exposed to a daily 12-h light–dark cycle, and fed water and rat chow (Milne Stockfeeders, Perth, Australia) *ad libitum*. This study was approved by the Royal Perth Hospital Animal Ethics Committee.

Surgical procedures

The rats were anaesthetized by an intraperitoneal injection of pentobarbitone sodium 50 mg per kg body-weight. They were then placed on a heating pad and a midline incision was made in the abdomen. The animals were randomized to either serve as controls (sham surgery) or to be subjected to a standardized ischaemia–reperfusion injury (suprarenal aorta occluded for 1 h followed by 1 h of reperfusion). Standardized circumferential and full-thickness biopsies were taken from the proximal jejunum of animals in the control group. The suprarenal aortas of the remaining animals were occluded with a vascular clamp before closure of the abdomen. After 1 h, the abdomens were reopened and standardized circumferential and full-thickness biopsies were taken from the proximal jejunum (ischaemic samples). The vascular clamps were then removed from the aorta and the abdomens were closed. After 1 h of reperfusion, the abdomens were reopened and further standardized circumferential and full-thickness biopsies were taken from the proximal jejunum (reperfused samples).

Harvesting of tissues

The ischaemic samples were divided into portions 0·5 and 3·0 cm long. The 0·5-cm segments were slit down the mesenteric border, embedded in Optimal Cutting Temperature (OCT) Compound (Sakura Finetechnical, Tokyo, Japan) and immediately snap-frozen in liquid nitrogen for immunohistochemistry. The 3·0-cm segments were weighed, slit down the mesenteric border and the mucosa was stripped away from the submucosa using a glass slide (depth confirmed by histology). The samples of mucosa were weighed, placed in 5 ml of homogenizing buffer (potassium hydrogen phosphate 125 mmol/l, sucrose 330 mmol/l, dithiothreitol 2 mmol/l, pH 7·6) and homogenized (Ultra Turrax; Janke and Kunkel, Staufen, Germany).

The reperfused samples and control samples were divided into portions 0·5, 3·0 and 10·0 cm long. The 0·5- and 3·0-cm segments were treated in the manner described for the ischaemic samples. Enterocytes were isolated from the 10·0-cm segments using the method described by Weiser[7]. Briefly, the segments of bowel were flushed with normal saline, filled with disrupting solution (potassium chloride 1·5 mmol/l, sodium chloride 96 mmol/l, sodium citrate 27 mmol/l, potassium dihydrogen phosphate 8 mmol/l, disodium hydrogen phosphate 5·6 mmol/l, pH 7·3) and incubated for 15 min at 37°C. The disrupting solution was replaced with collection buffer (sodium chloride 13·6 mmol/l, potassium chloride 0·26 mmol/l, potassium dihydrogen phosphate 0·14 mmol/l, disodium hydrogen phosphate 0·81 mmol/l, ethylenediamine tetra-acetic acid 1·5 mmol/l, dithiothreitol 0·5 mmol/l, pH 7·4) and the segments of bowel were incubated for a further 15 min. The segments were patted with the finger tips, the isolated enterocytes were collected into a centrifuge tube and the tubes were centrifuged at 500*g* for 5 min at 4°C. The isolated enterocytes were immediately snap-frozen in liquid nitrogen and stored at −70°C.

Paper accepted 5 March 1998

Immunohistochemistry

The samples frozen in optimal cutting temperature compound were sectioned on to glass slides at 6 μm using an Ames Cryostat II (Miles). Immunohistochemical staining was performed using an indirect immunoperoxidase technique[8]. The primary antibody was a mouse antirat CD44 antibody (MRC OX-50; Serotec, Oxford, UK) diluted 1 : 100. The secondary antibody consisted of biotinylated sheep antimouse immunoglobulins (Amersham Australia, Sydney, Australia) containing 10 per cent normal rat serum. The tertiary antibody was a streptavidin–horseradish peroxidase conjugate (Amersham Australia). Sections were counterstained with haematoxylin and peroxidase-positive cells were identified morphometrically by brown staining around the cytoplasm. Positive cells were expressed as the number of positive cells per 1000 enterocytes. At least ten villi or 1000 enterocytes were counted per section.

Biochemistry

Aliquots of the mucosal homogenates were taken to estimate protein content by the method of Lowry *et al.*[9] using bovine serum albumin as the standard and DNA content by the method of Larbarca and Paigen[10] using calf thymus DNA as the standard.

Molecular biology

RNA was separated from the isolated enterocytes using RNAzol B (Bresatec, Adelaide, Australia). RNA integrity was confirmed by electrophoresis on a 1 per cent denaturing agarose gel. The RNA content was measured by ultraviolet spectrophotometry and samples were then diluted to 1 μg/μl with diethyl pyrocarbonate-treated water. The RNA was reverse transcribed using avian myeloblastosis virus reverse transcriptase (Promega, Sydney, Australia) and 5 μl of the resultant complementary DNA was subjected to polymerase chain reaction (PCR). The PCR reaction mix contained deoxyribonucleoside 5′-triphosphates 200 μmol/l, 1 × PCR buffer (Boehringer Mannheim, Sydney, Australia), 0·5 units Taq DNA polymerase (Boehringer Mannheim) and 0·16 μmmol/l each of the forward and reverse primers. The forward primer sequence for CD44 was 5′GGTGCATTTGGTGAACAAGG3′ and the reverse primer sequence was 5′AAAGGACCTCCAGGGTTTGA3′, resulting in a product of 676 base pairs[11]. β-actin mRNA was used as an internal control. The forward primer sequence for β-actin was 5′ATGGATGACGATATCGCTG3′ and the reverse primer sequence was 5′ATGAGGTAGTCTGTCAGGT3′, resulting in a product of 568 base pairs[12].

The PCR was carried out for 45 s at 94°C, 45 s at 55°C and 90 s at 72°C for 35 cycles. Preliminary work indicated that the amplification was in the exponential phase at 35 cycles. Aliquots of the PCR reaction mixes (5 μl) were electrophoresed on 6 per cent polyacrylamide gels, stained with SYBR Green I (1 : 10 000; Molecular Probes, Eugene, USA) and scanned using the FluorImager SI computer package (Molecular Dynamics, Melbourne, Australia). The intensity of the product bands was measured using Image Quant software (Molecular Dynamics) and expressed as a ratio of CD44 to β-actin products.

Statistical analysis

Results are expressed as mean(s.d.). Comparisons were made using the Mann–Whitney *U* test for independent samples and the Wilcoxon matched pairs signed rank test for related samples. A probability of a type I error of less than 5 per cent was considered to be statistically significant.

Table 1 Effect of ischaemia–reperfusion on the jejunal mucosa

	Control ($n = 8$)	Ischaemia–reperfusion injury ($n = 8$)	
		Ischaemic	Reperfused
Protein content (μg/mg)	38·14(7·54)	36·53(9·19)	24·47(10·27)
DNA content (μg/mg)	7·54(2·18)	6·49(2·45)	3·47(1·98)

Values are mean(s.d.)

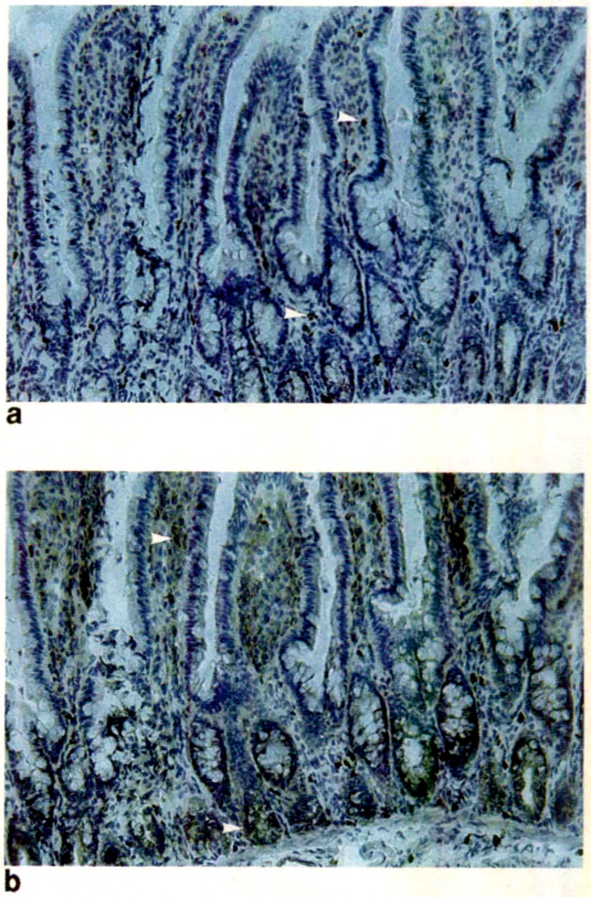

Fig. 1 Effect of ischaemia–reperfusion on CD44 expression in the jejunum. **a** Negative control; note the granular endogenous peroxidase (arrows). **b** CD44 expression around the villous tips and crypts; positive cells were identified by brown staining (arrows) around the cytoplasm (haematoxylin counterstain; original magnification × 40)

Results

Reperfusion significantly damaged the jejunal mucosa (*Table 1*). Mucosal protein content was lower after reperfusion compared with that in both the control group ($z = -2\cdot31$, $P = 0\cdot02$) and the ischaemic samples ($z = -2\cdot52$, $P = 0\cdot01$). In addition, the reperfused samples had a lower mucosal DNA content than the control samples ($z = -2\cdot62$, $P = 0\cdot01$) and the ischaemic samples ($z = -2\cdot38$, $P = 0\cdot02$). Histological examination confirmed that 1 h of ischaemia followed by 1 h of reperfusion produced ischaemia–reperfusion injury. The degree of intestinal tissue damage ranged from the development of subepithelial space at the villous tip, to epithelial lifting along the villous sides, i.e. grade I–III lesions[13,14].

The expression of cell surface CD44 protein was decreased after ischaemia–reperfusion injury. In the control group 119·9(39·3) cells per 1000 enterocytes expressed surface CD44, while 73·5 (40·0) cells were stained in the ischaemic samples ($z = -1\cdot99$, $P = 0\cdot04$). Reperfusion tended to decrease CD44 surface expression (76·4(30·6) positive cells). However, this was not significant compared with either the control group ($z = -1\cdot78$, $P = 0\cdot07$) or the ischaemic samples ($z = -0\cdot14$, $P = 0\cdot89$). This coincided with a significant decrease in the ratio of cytoplasmic CD44 to β-actin mRNA within isolated enterocytes: 1·00(0·14) in the control group *versus* 0·73(0·25) in reperfused samples ($z = -2\cdot31$, $P = 0\cdot02$). CD44 was expressed in the crypts and villous tips of the jejunum in rats after ischaemia–reperfusion injury (*Fig. 1*).

Discussion

It was found that 1 h of ischaemia followed by 1 h of reperfusion produced morphological and biochemical changes within the jejunum. Ischaemia–reperfusion injury impaired gut cellularity, as demonstrated by reduced mucosal protein and DNA contents. Furthermore, ischaemia–reperfusion injury decreased the expression of CD44 mRNA and cell surface receptors. This raises the possibility that ischaemia–reperfusion injury impairs gut integrity and gut barrier function by reducing cell–cell and cell–matrix interactions. Possible explanations for these findings are that the decreased expression of CD44 is indicative of mucosal cell death due to ischaemia–reperfusion injury, or that the reperfusion period was not long enough to detect ischaemia–reperfusion injury-induced PMN infiltration.

CD44 plays an important role in biological processes such as haematopoiesis, lymphocyte activation, cellular migration, tumour progression and metastasis[15]. In addition, CD44 has been implicated in signal transduction[16], enhancement of natural killer cell cytotoxic activity[17] and regulation of murine B cell effector functions[18]. CD44 is a widely distributed cell surface glycoprotein whose principal ligand has been identified as hyaluronan, a major component of the extracellular matrix[18]. Analysis of canine epithelium in the kidney has shown that the distribution of CD44 is restricted to the basolateral domain of polarized epithelial cells, supporting the belief that CD44 plays a role in interepithelial interactions[19].

The site of expression of CD44 is of crucial importance. In normal small intestine, CD44 expression is seen on many different cells within the lamina propria. However, expression on epithelial cells is restricted to the region of cell division in the base of the crypts[20]. This distribution, combined with the established functions of CD44, suggests an involvement in the maintenance of villous integrity[3,21]. This is supported by Jun *et al.*[22] who found that CD44 expression was most prominent within tight junctions of rats with experimental glomerulonephritis.

This study showed that ischaemia–reperfusion injury decreased CD44 expression by villous epithelial cells. CD44 expression near the villous tips was first reported by Uff *et al.*[3] during small bowel allograft rejection. Such changes in the pattern of CD44 expression may be related to alterations in extracellular matrix components and loss of villous integrity. This is because a major function of the extracellular matrix is to provide structural support to the villi[20]. The extracellular matrix contains hyaluronan molecules which have large hydrodynamic volumes that are able to trap substantial amounts of water and therefore influence tissue swelling[23]. CD44 expression plays an important role in the maintenance of hyaluronan homoeostasis as demonstrated by impaired tissue repair and failure of the epidermis to undergo hyperplasia in CD44 knockout mice[24].

Cytokines may influence the expression of CD44 on villous epithelial cells. Uff *et al.*[3] suggest that alterations in the pattern of CD44 expression may be due to changes in the cytokine profile of damaged mucosa. Tumour necrosis factor (TNF) α and interferon γ have been shown to up-regulate the expression of various CD44 isoforms[25,26]. This is not surprising as these cytokines are known to play an integral role in leucocyte activation and inflammation[25–27], which are also functions of CD44. In addition, it is interesting to note that ligation of hyaluronic acid and CD44 stimulates TNF-α mRNA transcript expression[28,29].

In conclusion, on the basis of the present findings it is postulated that ischaemia–reperfusion injury may impair the gut barrier by reducing normal CD44 functions. This results in inadequate infiltration of the mucosal tissues by inflammatory cells, a loss of villous integrity and a breakdown in gut barrier function. Further studies on the interactions of CD44 and other adhesion molecules involved in cell–extracellular matrix binding may improve understanding of the mechanisms underlying failure of the gut barrier.

Background The mortality rate associated with ruptured abdominal aortic aneurysm (AAA) remains high. The objective of this study was to assess the feasibility of population screening for AAA.

Methods In an area with a mixed rural and industrialized population of 60 000 inhabitants, all 23 general practitioners (GPs) participated. The GPs selected from their patient lists men aged 60–80 years. Men whose condition was suitable for aortic surgery were invited for screening by a single postal letter. All men responding had aortic ultrasonography in or close to the GP surgery. Diagnosis of AAA was established when the aortic diameter was 30 mm or greater. Referral for surgery was advised for an aortic diameter of 50 mm or greater.

Results Of 2914 invitations, 2419 men had ultrasonography, resulting in an attendance rate of 83·0 per cent. A total of 2416 aortic measurements were made; 196 aortic aneurysms were diagnosed (prevalence 8·1 per cent). In 40 men the aortic diameter was over 50 mm.

Conclusion Ultrasonographic screening for AAA is feasible in a primary care setting.

The mortality rate associated with ruptured abdominal aneurysm (AAA) remains high. Survival is estimated to be only 10–20 per cent[1–5]. The incidence of ruptured AAA is increasing and this can only partially be explained by the gradual ageing of the population[6–13]. AAA causes almost 2 per cent of all deaths in men over the age of 60 years in England and Wales[14]. The mortality rate is threefold higher in men compared with women, who are affected by AAA at an age 10 years older[3,4,6,8,11,15–17]. The reported prevalence varies with the definition of AAA, the geographical area and the population.

Ultrasonography is very effective in the detection of AAA[18–20]. Screening asymptomatic individuals offers the best chance for detection and elective treatment of AAA, resulting in a substantial reduction in the incidence of rupture[21]. The risk of rupture increases with the AAA size, which therefore determines the timing of surgical intervention[2,22–25]. Elective operative repair is the standard treatment, with a perioperative mortality rate of approximately 5 per cent[26–30].

AAA causes significant mortality and morbidity in elderly men; detection of the condition is simple and accurate, and an effective treatment is available[31]. Therefore a public screening programme should be considered[14,21,32,33]. The design of a programme requires information on prevalence, health care availability and patient compliance. A study was therefore performed to assess the feasibility of an ultrasonographic AAA screening programme in a primary care setting. The main objectives were to determine the attendance rate and the prevalence of AAA in men over 60 years of age[7,33]. An upper age limit of 80 years was chosen in view of the increased mortality rate of elective AAA repair and a limited life expectancy[26,34].

Patients and methods

Three neighbouring districts in the east of the Netherlands were selected for the AAA screening study, involving a mixed rural and industrialized population of 60 000. Full participation was obtained from all 23 general practitioners (GPs), serving the inhabitants of the area.

All men aged 60–80 years were selected from the GP patient registers, a total of 3098. The GPs excluded all men who previously had AAA repair and those whose condition was judged to be unsuitable for AAA repair. The most common reasons for exclusion were respiratory insufficiency with continuous oxygen therapy, cardiac failure, disseminated malignancy and poor mental state, mostly due to advanced dementia. This resulted in exclusion of 184 selected men (5·9 per cent). The remaining men were sent a single postal invitation, which included information on AAA, ultrasonography and the screening study. The invitations were signed by the local GP and the study coordinator. A telephone number was supplied for further information and logistic arrangements. Non-responders were not contacted a second time.

Abdominal aortic investigations were carried out with a portable B-mode grey scale machine with a 3·75-MHz transducer (TOSBEE; Toshiba Medical Systems, Woerden, The Netherlands). The scanner was transported to locations adjacent or close to the GP surgeries, such as local health care buildings. Imaging was performed by one of four experienced technicians, recruited from the division of ultrasonography of the Department of Radiology, St Radboud University Hospital. The most dilated segment of the abdominal aorta was identified by longitudinal scanning from the diaphragm to the aortic bifurcation. The maximum diameter of the infrarenal and suprarenal abdominal aorta was measured in both transverse and anteroposterior directions[35,36].

A diagnosis of AAA was established when an aortic diameter of 30 mm or more was measured. Following AAA detection the GP was informed. For AAAs with a diameter of 50 mm or greater, referral to a regional hospital was advised for elective aneurysm repair. Ultrasonographic follow-up is continuing every 6 months for AAAs less than 50 mm. During follow-up, referral is advised if the aneurysm becomes symptomatic, the diameter increases to 50 mm or more and/or the growth rate is over

Paper accepted 26 February 1998

10 mm/year. The study was approved by the ethics committee of St Radboud University Hospital.

Results

A total of 2914 men were invited for aortic screening. Ultrasonographic investigation was performed in 2419 cases, resulting in an attendance rate of 83·0 per cent. There was little variation in compliance between the different areas with attendance rates of 81·8, 82·3 and 84·9 per cent.

Complete aortic measurement was achieved in 2416 men (99·9 per cent). In one, urinary bladder dilatation with megaureters made visualization of the aorta impossible. In a second patient extreme obesity in combination with bowel gas interfered with measurement of the suprarenal aorta. Because of chorea a third patient was unable to maintain a supine position during the investigation. The distribution of aortic diameters is shown in *Fig. 1*. In 196 men the infrarenal aortic diameter was 30 mm or greater; the prevalence of AAA was therefore 8·1 per cent. Stratification of detected AAAs according to age did not show an increase in AAA prevalence with age (*Fig. 2*). Of the 196 AAAs detected 40 were 50 mm or greater in diameter (prevalence 1·7 per cent). The distribution of larger aneurysms was also not influenced by age. These 40 patients were referred for

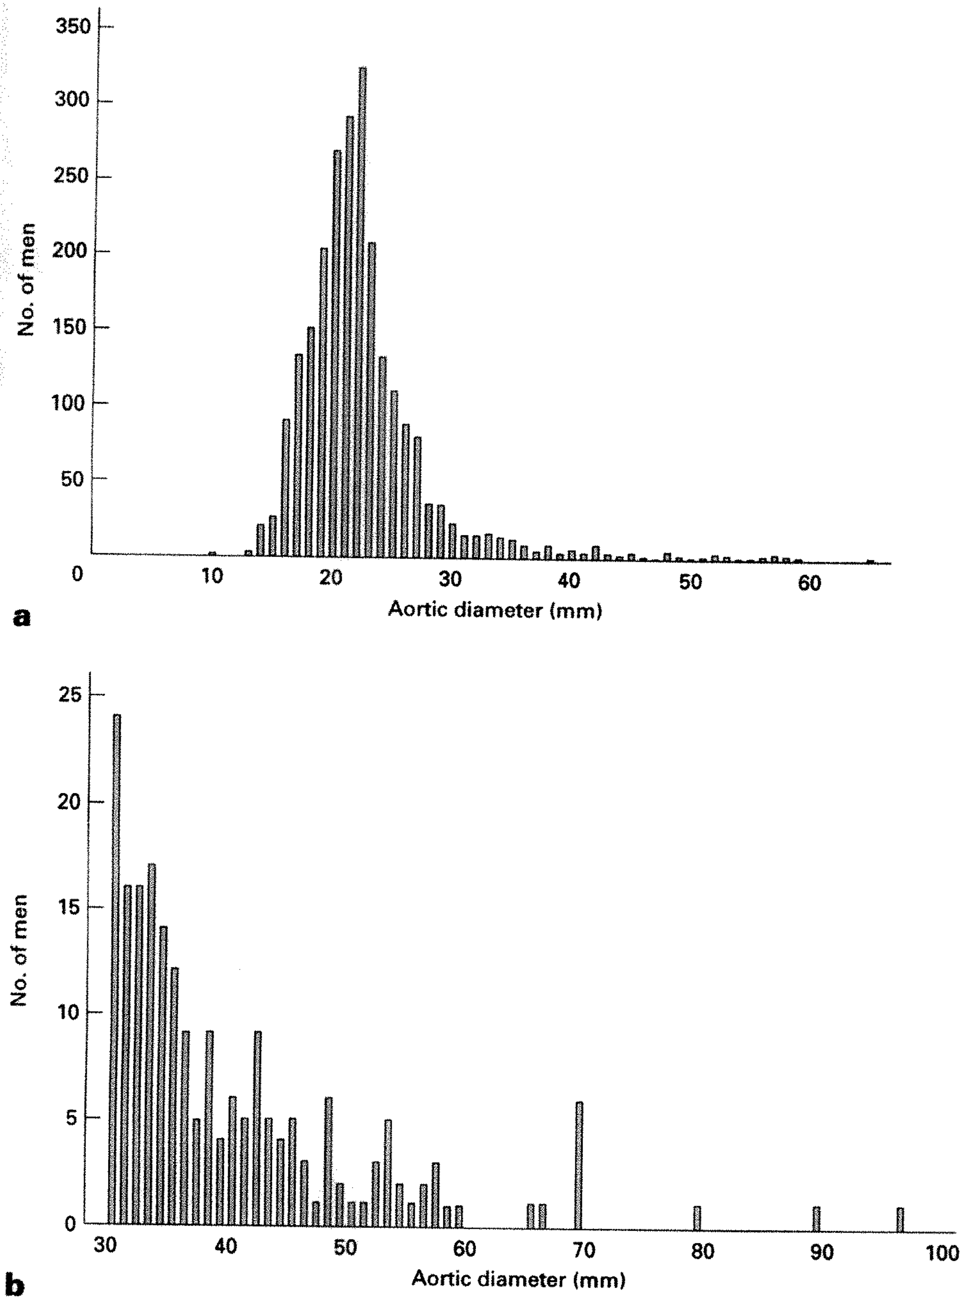

Fig. 1 a Distribution of maximum infrarenal abdominal aortic diameters in 2416 men aged 60–80 years. b Distribution of maximum infrarenal abdominal aortic diameters of 30 mm or more

surgery. Two men did not have an operation; one refused elective repair after being informed about risks and the other was not thought fit enough. Thirty-eight men underwent elective aneurysm repair; one died within 30 days following wound complications and multiple organ failure. Another patient died from pneumonia 2 months after operation. Follow-up scans over 6–18 months in the 156 men with an AAA less than 50 mm in diameter have resulted in another three elective aneurysm repairs.

Discussion

This study confirms that AAA is a fairly common condition in men aged over 60 years. Direct comparison of the prevalence found in this programme with that in other reports is complicated by differences in the observed population and diverse definitions[35–37]. An analysis of the results, defining AAA as a distal aortic diameter of at least 50 per cent more than that of the proximal aortic diameter and/or an absolute infrarenal diameter of 30 mm or more, results in a prevalence of 9·7 per cent (235 of 2416). If the absolute threshold is raised to a diameter of 35 mm the prevalence decreases to 6·6 per cent. These results correspond with the outcome of other studies in open populations as shown in *Table 1*[21,38–47]. The high attendance rate in this study compares favourably with those reported from similar screening programmes, mostly conducted in the UK and Northern Europe. In other population screening studies in the

*Disregarding the absolute aortic diameter, an abdominal aortic aneurysm (AAA) was also considered to be present when the maximal diameter of a dilated segment of the aorta was 5 mm or more greater than the proximal suprarenal aortic diameter; †disregarding the absolute aortic diameter, an AAA was also considered to be present when the maximal diameter of a dilated segment of the aorta was equal to or greater than 150 per cent of the proximal aortic diameter. trans, Transverse; max, maximum; diam, diameter (not specified according to direction of measurement); a.p., anteroposterior

Netherlands, such as for breast cancer, the compliance tends to be high in comparison with other countries. This can be attributed to population differences. Two factors in the design of the present study are considered to have contributed to the high compliance. First, the programme was actively supported by the local GPs, who also signed the invitations for screening, and second, ultrasonography was performed locally and was therefore easily accessible.

The costs of the programme ensuing from 3000 postal invitations, 2400 ultrasonographic examinations, GP reimbursement and communication amount to £75 000, corresponding to £31 per individual screened or £383 per aneurysm detected. Taking into account that 184 (5·9 per cent) of the 3098 men aged 60–80 years were not invited for AAA screening for medical reasons and the attendance rate of those who were invited was 83·0 per cent, a total of 78·1 per cent (2419 of 3098) of the population at risk was actually screened.

Primary care-based ultrasonographic screening of men aged 60–80 years in a mixed rural and industrialized population results in a high attendance rate and revealed a high prevalence of asymptomatic AAA. The screening programme was inexpensive and well received both by patients and GPs. The assumed substantial reduction of death from ruptured AAA would support the idea of a large-scale AAA screening study of the population at risk[21].

Histological study of colonic ischaemia after aortic surgery

M. WELCH, M. S. BAGUNEID, R. F. McMAHON, P. D. F. DODD, P. E. FULFORD, G. D. GRIFFITHS and M. G. WALKER

Department of Vascular Surgery, Manchester Royal Infirmary and Medical School, Oxford Road, Manchester M13 9WL, UK
Correspondence to: Professor M. G. Walker

Background Colonic ischaemia is a well documented complication of abdominal aortic reconstruction. In this prospective study patients had routine preoperative and postoperative colonoscopy and biopsy, in order to determine the true incidence and implications.

Methods Fifty-six patients undergoing elective infrarenal aortic surgery, 28 for aneurysm and 28 for occlusive disease, had colonoscopy and biopsy before and 1 week after operation.

Results Colonic ischaemia was identified histologically in biopsies from 16 (30 per cent) of 53 patients. Almost half the patients had normal macroscopic appearances. Two factors exhibited a statistically significant association with the development of ischaemia: prolonged cross-clamp time ($P < 0{\cdot}05$) and postoperative diarrhoea ($P < 0{\cdot}001$). Co-morbidity was much higher in patients with colonic ischaemia ($P < 0{\cdot}005$). Overall morbidity was significantly greater in the aneurysm group ($P < 0{\cdot}05$).

Conclusion Colonic ischaemia is common after aortic reconstruction. When suspected, colonoscopy with biopsy is diagnostic.

Abdominal aortic reconstruction is a routine vascular procedure, but is still associated with significant morbidity and a mortality rate approaching 6 per cent for elective aneurysm repair[1–4]. First documented in 1954[5], postoperative colonic ischaemia remains a serious potential complication; the reported incidence varies from 0 to 32 per cent[6]. Important predisposing factors are listed in *Table 1*[7–19]. The commonest reported symptom is diarrhoea with or without blood, usually commencing within 48 h of surgery[19,20]. Absence of diarrhoea is documented[18] and may present diagnostic difficulty.

The aim of this study was to examine, by colonoscopy and biopsy, the incidence of overt and subclinical postoperative colonic ischaemia in an unselected group of patients undergoing elective infrarenal aortic surgery, and to identify predictive factors.

Patients and methods

All patients undergoing elective abdominal aortic surgery involving infrarenal cross-clamping were included after giving their informed consent. Ethics committee approval was obtained before commencement of the study. Exclusion criteria were: a history of previous aortic surgery, colonic disease or resection, and intraoperative diagnosis of colonic pathology.

Venous blood was taken for measurement of baseline haematology and biochemistry. Arterial blood was sampled for measurement of blood gases, and 24-h urine collection was performed to determine creatinine clearance. The night before surgery patients were given a phosphate enema to evacuate the distal colon and rectum.

Table 1 Factors predisposing to postoperative colonic ischaemia[7–19]

Inferior mesenteric arterial ligation
Severe stenosis or occlusion of the superior mesenteric artery, internal iliac arteries or other collateral channels
Aortoiliac steal syndrome
Operative damage to vital collaterals, mesentery or colon
Previous colectomy with sacrifice of middle colic artery
Prolonged hypotension with resultant hypoperfusion
Operation for ruptured aneurysm
Embolization of atheromatous debris or cholesterol
Prolonged cross-clamp time

A standard general anaesthetic technique was used, with non-invasive monitoring of pulse, respiratory rate, tidal volume, oxygen saturation (S_{aO_2}) and end-tidal carbon dioxide. Central venous pressure and S_{aO_2} were measured directly by means of internal jugular venous and radial arterial lines, and urine output was monitored continuously.

After induction of anaesthesia, patients were placed in the left lateral position and a limited colonoscopy performed using an Olympus CF-10 L colonoscope (Olympus Optical, London, UK). Note was made of visual appearances, and biopsies were taken at 20, 30 and 40 cm from the anal verge. Specimens were immediately fixed in 10 per cent formalin solution for later examination by the same consultant histopathologist.

All operations were performed using a standard technique of aortic graft insertion. Aortic aneurysms were replaced by inlay of straight or bifurcated grafts as necessary. Aortic occlusive disease was bypassed using an end-to-side proximal anastomosis. At operation, note was made of the patency of the superior mesenteric artery (SMA), inferior mesenteric artery (IMA) and marginal arteries. Cross-clamp time was documented together with whether or not the IMA or internal iliac arteries were ligated. All patients except one had preservation of at least one internal iliac artery. The incidence of significant hypotension, defined as systolic blood pressure less than 85 mmHg lasting longer than 10 min, was documented for the intervals before, during and after cross-clamping, and after operation.

Fluid administration was governed by anaesthetic staff, losses being replaced by colloid, crystalloid and blood, as required. Routine postoperative management included intravenous fluids, analgesia using intravenous morphine via a patient-controlled administration pump, and monitoring of pulse, blood pressure, central venous pressure, urine output and peripheral pulses. The incidence of postoperative diarrhoea was documented, as were cardiac, respiratory, renal and circulatory complications.

Haematology and serum biochemistry were measured on days 1, 2, 3 and 7 after operation; 24-h urine collections were also made for the purpose of measuring creatinine clearance.

Colonoscopy with biopsies was repeated under sedation 1 week after surgery.

Results

Fifty-six patients were studied (male : female ratio 3 : 1, mean age 64 (range 46–80) years). The mean age of those

Paper accepted 20 January 1998

undergoing surgery for aneurysm was significantly greater than that of patients having an operation for occlusive disease (67 *versus* 60 years; $P<0{\cdot}005$, two-tailed unpaired *t* test).

Preoperative arteriography was available in 35 patients (63 per cent), seven with an aneurysm and 28 with occlusive disease. The SMA was patent in all patients. Seven had an occluded or stenosed IMA; 27 had at least one occluded or stenosed common iliac artery; and 19 had at least one occluded or stenosed internal iliac artery.

At operation the IMA was ligated in significantly more patients in the aneurysm group (all patients *versus* ten of 28; $P<0{\cdot}05$, two-tailed Fisher's exact test). Ligation of both the IMA and an internal iliac artery was necessary in five patients.

Cross-clamp time ranged from 20 to 87 (mean 38) min, and was almost 5 min longer in the aneurysm group (40 *versus* 35 min, $P=0{\cdot}06$, two-tailed unpaired *t* test).

Significant hypotension occurred in ten patients (18 per cent), significantly more in the aneurysm group (nine of 28 *versus* one of 28; $P=0{\cdot}01$, Fisher's exact test). Mild to moderate diarrhoea occurred in 19 patients (34 per cent); three had associated bleeding, one of whom progressed to frank necrosis. The incidence was similar in aneurysm and occlusive groups (11 of 28 *versus* eight of 28). Stool culture for pathogens including *Clostridium difficile* was negative in all patients who had diarrhoea.

Colonic histology (Fig. 1)

All patients had normal macroscopic and microscopic appearances of colonic mucosa before surgery. Postoperative ischaemia was suggested on macroscopic appearances in 13 patients (25 per cent); however, four of these had oedema or pallor of the mucosa but normal histology. Ischaemia was diagnosed by microscopy in 16 patients (30 per cent). Of these, seven patients had normal mucosa macroscopically. There was no significant difference in the incidence of ischaemia between patients with aneurysm or occlusive disease (ten of 26 *versus* six of 27; $P>0{\cdot}05$, Fisher's exact test). In each patient, histological appearances of biopsies taken at the specified levels showed no differences in the distribution of ischaemia.

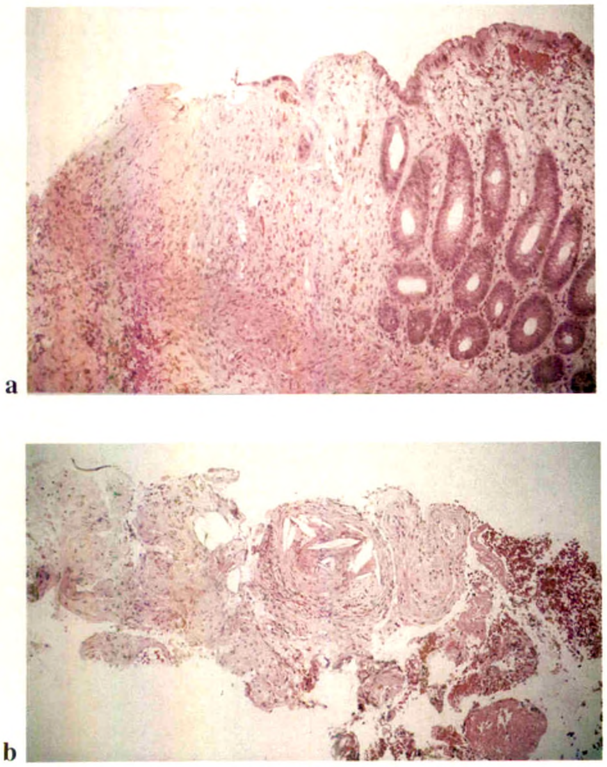

Fig. 1 a Colonic mucosa in which there is superficial ulceration and granulation tissue (to the left) along with acute inflammation of the adjacent epithelium (to the right). **b** Section from the base of the ulcer in **a** showing cholesterol emboli in the arteriole. Haematoxylin and eosin stain, original magnification ×40

Complications

Overall morbidity, excluding colonic ischaemia, was 34 per cent, significantly greater following aneurysm repair (13 of 28 *versus* six of 28 patients; $P<0{\cdot}05$, Fisher's exact test). Cardiac complications occurred in five patients (myocardial infarction, two; heart failure, two; significant dysrhythmia, one); three of these were fatal. Respiratory complications occurred in three of 56 patients (5 per cent). Three patients experienced major vascular morbidity: two had critical ischaemia of one foot which recovered, and in one patient one limb of a bifurcated graft was occluded at 24 h, requiring further surgery. There were no haemorrhagic complications. Gastrointestinal complications included one fatal colonic infarction on the ninth postoperative day and one perforated gastric ulcer on day 10, with recovery after partial gastrectomy. Most renal complications were subclinical and were diagnosed on the basis of changes in serum creatinine or creatinine clearance (30 per cent rise in the former or decrease in the latter sustained for a minimum of 2 days); all but one patient recovered within 1 week. No patient required dialysis, nor were any deaths directly attributable to renal failure.

Patients with colonic ischaemia

Comparing patients with and without colonic ischaemia, there were no differences in age, sex and preoperative arterial patencies (*Fig. 2*). At operation, a palpable pulse was noted in the IMA in nine of 16 patients who developed colonic ischaemia compared with 33 of 40 who did not ($P<0{\cdot}05$, Fisher's exact test). All patients had pulsatile marginal arteries. Although IMA ligation was performed more frequently in patients who developed

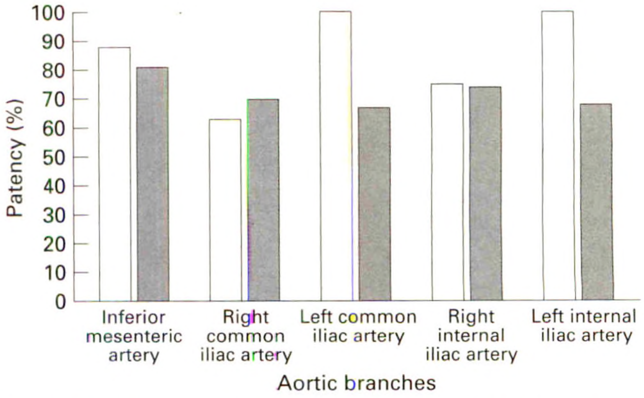

Fig. 2 Patency of aortic branches at preoperative angiography in patients with (□) and without (▨) colonic ischaemia. There were no significant differences in patency between the two groups

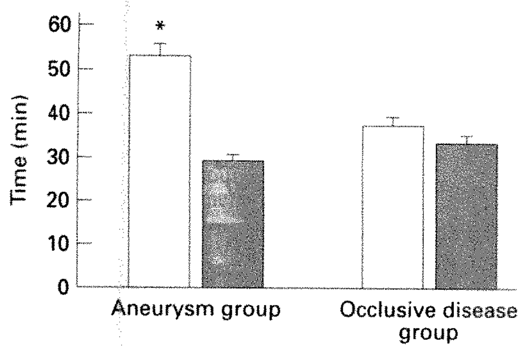

Fig. 3 Aortic cross-clamp time in patients with (□) and without (▨) colonic ischaemia. $P < 0{\cdot}05$ *versus* patients without colonic ischaemia (Mann–Whitney *U* test)

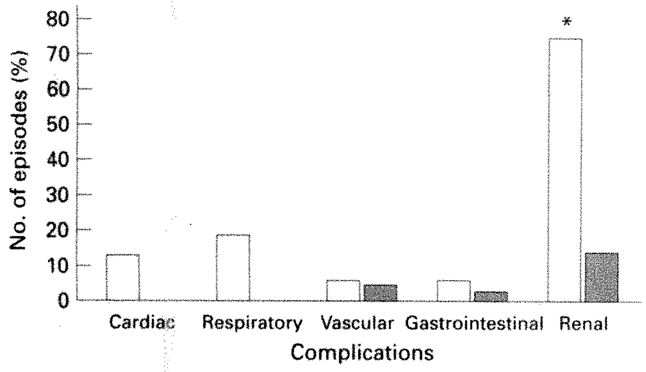

Fig. 4 Morbidity in patients with (□) and without (▨) colonic ischaemia. $P < 0{\cdot}05$ *versus* patients without colonic ischaemia (Fisher's exact test)

colonic ischaemia (13 of 16 *versus* 25 of 40), this did not reach statistical significance.

Cross-clamp time was significantly longer in patients who developed ischaemia (mean 45 *versus* 35 min; $P < 0{\cdot}05$, Mann–Whitney *U* test). This difference occurred in the patients with aneurysm (mean 53 *versus* 29 min; $P < 0{\cdot}05$) (*Fig. 3*). Significant hypotension occurred more often in patients who developed colonic ischaemia (five of 16 *versus* five of 40), although this difference was not significant. Postoperative diarrhoea occurred more often only in patients with ischaemia (14 of 16 *versus* five of 40; $P < 0{\cdot}001$, Fisher's exact test). Mortality and overall morbidity rates were also greater in the ischaemia group (13 of 16 *versus* six of 37; $P < 0{\cdot}005$, Fisher's exact test) (*Fig. 4*).

Discussion

The majority of reports about postoperative colonic ischaemia following aortic surgery are anecdotal or retrospective. Ernst *et al.*[8] colonoscoped 50 consecutive patients within 4 days of aortic surgery, noting macroscopic changes of ischaemia; Zelenock *et al.*[21] performed colonoscopy in 100 consecutive patients within 48 h of surgery. The incidence of ischaemia in these studies was 6 and 3 per cent respectively, but they relied on visual assessment by the endoscopist and these values were almost certainly inaccurate.

A more scientific method of diagnosing ischaemia is by histological examination. Marston *et al.*[22] described three patterns of ischaemic colitis: infarction of the colon, ischaemic stricture and 'transient ischaemic colitis'. Bicks *et al.*[23] also agreed with the concept of 'transient' ischaemia: diarrhoea which occurred 6–8 days after operation, with a spectrum of proctoscopic findings varying between normal, pallor, non-specific oedema, granularity, friability and punctate ulceration. Others have reported non-specific sigmoidoscopic appearances similar to those of ulcerative colitis[24,25]. Macroscopic signs of transient mucosal ischaemia may include non-specific diffuse hyperaemia with multiple submucosal haemorrhagic spots, oedema, or small erosions or ulcers[26]. It was felt that such lesions had no clinical significance. However, patients with subclinical ischaemia may develop mucosal disruption at macroscopic and microscopic levels, and may be susceptible to development of sepsis from enteric organisms and multiple organ failure.

The importance of histological assessment in the diagnosis of ischaemic colitis was emphasized by McBurney *et al.*[20]. In the present study all patients had normal macroscopic and microscopic appearances before operation. Of 13 patients (25 per cent) with abnormal postoperative macroscopic appearances, four had normal histology, therefore excluding ischaemia. However, ischaemia was diagnosed on the basis of histology in seven more patients, resulting in an overall incidence of 16 patients (30 per cent). This incidence is higher than that in any previously reported prospective study. Prospective studies that reported a high incidence of ischaemia are not comparable for various reasons: Fiddian-Green *et al.*[27] and Schiedler *et al.*[28] described incidences of 25 and 29 per cent respectively, but in selected patients considered to be at highest risk of developing colonic ischaemia. Krohg-Sorensen and Kvernebo[29] diagnosed ischaemia on the basis of symptoms in three of 16 patients (19 per cent), Meroni *et al.*[30] reported a 17 per cent incidence in only 18 patients, and a 13 per cent incidence was reported by Hagihara *et al.*[31] in a larger study.

Preoperative arteriography was not performed in most patients in this study, particularly before aneurysm repair. Although important information may be obtained[9,32] preoperative arteriography does not reduce morbidity and mortality rates[3] and in this study it failed to help predict which patients would develop postoperative colonic ischaemia.

The importance of the fate of the IMA is unknown. IMA clamping reduces colonic blood flow, particularly in patients undergoing surgery for occlusive disease[29]. Ernst *et al.*[33] described a critical IMA stump pressure of 40 mmHg, below which ischaemia would develop after IMA ligation, but in their study only one such patient had ischaemic colitis. Ernst and colleagues reported previously that colonic ischaemia may still develop when the IMA is preserved[8]. Others found that ligation of a patent IMA did not increase the likelihood of ischaemic colitis, and that IMA stump pressure measurement was unreliable[28]. Zelenock *et al.*[21] suggested that ischaemia was less likely if the IMA was reimplanted; one large retrospective study found a lower incidence of colonic infarction when a policy of routine IMA reimplantation was undertaken[6]. In the present study colonic ischaemia was more common in patients who had IMA ligation (although not significantly so). Reimplantation was never performed.

The importance of the duration of aortic clamping in the aetiology of colonic ischaemia is well recognized[19]. This is particularly important in patients with aneurysms, who do not have an adequate collateral circulation. In the present study, cross-clamp time was significantly longer in patients who developed ischaemia, mainly during aneurysm repair. The few published prospective studies disagree whether colonic ischaemia is more likely after surgery for aneurysm than for occlusive disease[8,28]. In the present study, patients who had aneurysm repair had a longer cross-clamp time and were significantly more likely to need IMA ligation. Perioperative hypotensive episodes were more frequent, diarrhoea more common and histological ischaemia more prevalent in patients who had aneurysm repair. Mortality and overall morbidity rates were also greater. Therefore, although colonic ischaemia did not develop in significantly more patients with aneurysm, risk factors for ischaemia were more common and postoperative mortality and morbidity rates were higher in this group.

Although a high incidence of colonic ischaemia was demonstrated in this study (30 per cent), progression to colonic infarction was rare; only one patient died from this complication. In this case, the patient's clinical state did not suggest that laparotomy was required. The severity of ischaemia cannot currently be predicted by histological means alone.

While in many cases, colonic ischaemia is truly transient and is not a major clinical problem, patients who have prolonged aortic cross-clamp, or who develop postoperative diarrhoea, would benefit from investigation. Sigmoid tonometry, which can detect intramural acidosis and thus ischaemia, might help determine which patients should undergo colonoscopy. When colonoscopy is deemed necessary, biopsy and histology should be performed. Although current basic histological stains do not fulfil any predictive role, a diagnosis of ischaemia is indicative of higher risk.

Comparison of duplex imaging and arteriography in the evaluation of lower limb arteries

S. ALY, K. SOMMERVILLE, M. ADISESHIAH, M. RAPHAEL, P. D. COLERIDGE SMITH and C. C. R. BISHOP

Department of Surgery, University College London and Medical School, Mortimer Street, London W1N 8AA, UK
Correspondence to: Mr S. Aly

Background The aim of this study was to assess the accuracy of duplex imaging, compared with arteriography, in detecting arterial disease distal to the renal arteries.

Methods Some 177 legs were studied in 90 patients (59 men, 31 women; median age 68 years) with peripheral arterial disease. Each patient had conventional intra-arterial angiography and duplex ultrasonography. Each leg was divided into 17 arterial segments, and the disease in each segment was quantified by measuring the peak systolic velocity ratio across any arterial lesion that was identified.

Results Compared with angiography, duplex imaging was able to detect arterial disease with an overall sensitivity of 92 per cent, specificity of 99 per cent, positive predictive value 91 per cent and negative predictive value 100 per cent, and with a κ value of 0·87 (95 per cent confidence interval (c.i.) 0·81–0·93). Duplex was able to determine the length of the arterial lesion with a sensitivity of 89 per cent and a specificity of 98 per cent with a κ value of 0·88 (95 per cent c.i. 0·86–0·90). When the surgeon's final management decision concerning each vascular lesion was used as the reference, duplex and arteriography were equivalent, with an accuracy of 84 per cent and 85 per cent respectively in identifying the management used.

Conclusion Duplex ultrasonography is reliable in detecting arterial lesions in peripheral arteries and could be used routinely in the initial evaluation of patients with lower limb arterial disease.

Arteriography has been regarded as the standard investigation for peripheral arterial disease[1]. Arteriography gives an anatomical representation but does not assess the functional obstruction presented by stenotic lesions. Recently duplex ultrasonography has replaced arteriography for investigation of carotid artery disease[2]. The use of duplex imaging to assess peripheral arterial stenoses, using the peak systolic velocity ratio (PSVR) across the lesion, has been described[3–5] and is reliable in the aortoiliac and femoropopliteal regions in comparison with arteriography[6–9]. In the intervening years there have been several technical improvements in duplex imaging equipment.

The aim of this study was to assess the accuracy of duplex imaging in detecting and assessing the severity and extent of lesions in the peripheral arterial tree in comparison with arteriography. A further aim was to assess the concordance of the clinical decision concerning patient management based on duplex results with that based on arteriography.

Patients and methods

Arterial duplex imaging and intra-arterial digital subtraction arteriography (IADSA) were performed in 90 patients (177 legs in 59 men and 31 women of median age 68 years). Eighty-one patients had intermittent claudication, one had ischaemic ulceration, and eight had rest pain. Ethics committee approval for this study was obtained from the University College London Medical School Ethics Committee and patients gave their written consent.

Duplex imaging was done by one of two trained vascular technologists who were unaware of the results of angiography. An Acuson scanner 128XP/10v (Acuson, Mountain View, California, USA) was used. A 2.5-MHz curvilinear and a 7-MHz linear array probe were used to examine the pelvic and the infrainguinal vessels respectively.

All patients fasted for 6 h before imaging to minimize the presence of bowel gas. With the patient supine, imaging was done from the infrarenal aorta to the ankle vessels. Colour flow was used to outline the arterial wall and any arterial lesions, and for each arterial segment the peak systolic velocity was obtained. The PSVR of any stenosis was derived by comparing the peak systolic velocity at the stenotic area to that of the prestenotic or poststenotic area. A PSVR of 2·0 was used to differentiate between a significant stenosis with more than 50 per cent reduction in luminal diameter and an insignificant stenosis with less than this. For the assessment, the peripheral arterial vessels were divided into 17 segments: common iliac, external and internal iliac, common femoral, superficial femoral and profunda femoris. The superficial femoral artery was divided into proximal, mid and distal segments, while the popliteal was divided into proximal and distal, and each crural vessel into proximal and ankle segments.

The length of iliac disease was determined by using the duplex ultrasonography measuring calliper; for femoropopliteal lesions a non-permanent skin marker was used to mark the proximal and distal ends of the arterial lesion detected by duplex imaging, and the distance between them was measured with a ruler.

IADSA was done within a week of duplex imaging by a consultant radiologist who was unaware of the duplex findings, using the Seldinger technique. A 7-Fr sheath was introduced through the common femoral artery, then a 5-Fr catheter was placed through the sheath to the aorta. Intra-arterial pressure measurements were not done routinely and only uniplanar views were obtained. The severity of stenosis was determined by dividing the diameter of the lumen by the diameter of the nearest normal segment. All IADSA films were reviewed and classified by two consultant radiologists separately. The length of the iliac

---

Paper accepted 20 January 1998

and femoropopliteal stenoses and occlusions were measured from the IADSA investigation.

To assess the clinical benefits and diagnostic reliability of duplex imaging compared with IADSA, five vascular surgeons were given 164 anonymous coded duplex and IADSA reports at two different sessions (6-month interval). All these reports were supported with a brief clinical history. Surgeons were asked to make a management decision based on either the arteriography or duplex reports.

The treatment that each patient received was established from the clinical notes and was used as the reference standard. The clinical decisions were classified into: conservative, balloon angioplasty, bypass surgery, combined therapy (balloon angioplasty and bypass surgery), thrombolysis or sympathectomy.

Statistical analysis

The sensitivity and specificity of duplex imaging compared with arteriography in detecting a non-significant (less than 50 per cent) and a significant (greater than 50 per cent) lesion or occlusion were calculated. The kappa (κ) statistic was computed to measure the level of agreement between the radiologists and technologists. For agreement by chance alone the κ value is 0 and for perfect agreement the κ value is 1. The 95 per cent confidence interval of κ values was also calculated.

Results

Some 3108 arterial segments in 177 legs (630 aortoiliac segment, 531 femoral, 885 femoropopliteal and 1062 run-off vessels in both calf and ankle) were examined in 90 patients. A total of 466 arterial lesions was identified and graded on arteriography, compared with 451 lesions identified and graded on duplex imaging. *Table 1* demonstrates the distribution of the arterial lesions in a two-way table of duplex and IADSA data.

In the aortoiliac region 570 of 630 segments were normal on both duplex and arteriography. Of 90 patients, two examinations of the iliac vessels were described as ‘difficult’ (because of the presence of bowel gas in one and obesity of the other patient; the common iliac artery and its bifurcation were not clearly seen). In the femoral artery 485 of 531 arterial segments were normal on both duplex scan and arteriography. Duplex was able to identify significant stenoses in the femoral arterial segment with a sensitivity and a specificity of 100 and 99 per cent respectively; for occlusions the sensitivity and specificity were 100 and 99 per cent (overall sensitivity and specificity in *Table 2*).

In the femoropopliteal region 648 segments were normal by both modalities. Some 213 arterial lesions were identified by both IADSA and duplex imaging. At the level of the run-off vessels 915 of 1062 segments were normal; 37 significant stenoses and 68 occlusions were recognized by both methods of investigation.

Table 1 Two-way table demonstrating the overall agreement between duplex imaging and arteriography

	Grading of IADSA based on diameter reduction (%)					
PSVR	Normal	< 20	20–< 50	50–99	Occlusion	Total
1	2618	8	2	10	19	2657
< 1·5	1	5	4	1	0	11
1·5–< 2	0	1	4	4	0	9
2	11	1	3	120	6	141
No pulse	12	0	0	6	272	290
Total	2642	15	13	141	297	3108

PSVR, peak systolic velocity ratio

Table 2 Statistical assessment of duplex imaging compared with intra-arterial digital subtraction angiography for all arterial segments

Artery	Sensitivity (%)	Specificity (%)	PPV (%)	NPV (%)	κ
AI	89	99	92	99	0·81 (0·92–0·70)
FA	100	99	95	100	0·94 (0·99–0·89)
FP	95	99	94	99	0·92 (0·94–0·90)
ROF	82	99	82	100	0·81 (0·87–0·75)
Overall	92	99	91	100	0·87 (0·93–0·81)

Values in parentheses are 95 per cent confidence interval. PPV, positive predictive value; NPV, negative predictive value; AI, aortoiliac; FA, femoral artery; FP, femoropopliteal region; ROF, run-off vessels

A summary of the overall accuracy of duplex scanning in all segments is shown in Table 2. Although a PSVR of 2·0 was used prospectively to discriminate between significant and insignificant stenosis, on receiver–operator curve (ROC) statistics, a PSVR of 1·8 was more sensitive in identifying a significant stenosis (*Fig. 1*).

Duplex and length of the arterial lesions

Some 807 arteries in 177 legs of 90 patients were examined (630 aortoiliac and 177 femoropopliteal). No disease was found in 624 arterial segments (559 aortoiliac and 65 femoropopliteal). Some 152 arterial lesions were detected by both methods of investigation (44 aortoiliac and 108 femoropopliteal), 89 lesions less than 5 cm in length (44 aortoiliac and 45 femoropopliteal), 31 lesions of 5–10 cm, and 32 lesions of more than 10 cm. Duplex imaging showed a sensitivity of 89 per cent, specificity of 98 per cent, positive predictive value of 92 per cent and

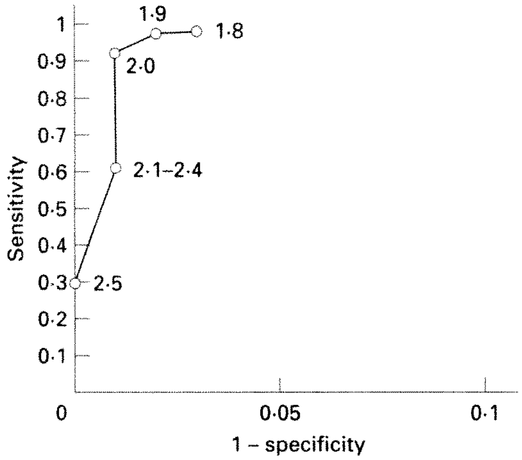

Fig. 1 Receiver–operator curve demonstrating the accuracy of various values of peak systolic velocity ratio (PSVR) in identifying significant stenosis. A PSVR of 1·8 is the most sensitive point for discriminating between significant and insignificant stenosis

Table 3 Accuracy of the decision based on duplex imaging compared with intra-arterial digital subtraction angiography when the actual treatment the patient received was used as a reference standard

		Accuracy					
Reference standard	Test	Surgeon 1	Surgeon 2	Surgeon 3	Surgeon 4	Surgeon 5	Mean
Final treatment received	Duplex	93	78	79	83	87	84
Final treatment received	IADSA	90	83	77	80	95	85
Decision based on IADSA	Duplex	98	89	88	85	95	91

IADSA, intra-arterial digital subtraction angiography

negative predictive value of 97 per cent compared with IADSA (reference standard) and κ value of 0·88 (95 per cent confidence interval 0·86–0·90).

Duplex and clinical decision

When the actual treatment the patient received was used as a reference standard, the mean accuracy of the clinical decision reached by the five vascular surgeons based on duplex data was 84 per cent and the accuracy based on IADSA was 85 per cent. When the surgeons' decision based on IADSA was used as the reference standard, the mean accuracy of duplex imaging was 91 per cent (*Table 3*).

Discussion

Arteriography continues to play a central role in the diagnosis and management of arterial disease. Despite advances in catheter design, contrast materials and techniques, arteriography remains invasive and carries both morbidity and mortality risks[9]. Recently, duplex imaging has reduced the indications for arteriography in the routine assessment of carotid artery disease and bypass graft patency. The relationship between the arterial diameter and age of the subject has been established by Jager *et al.*[3], who also reported that the peak aortic velocity decreases with age. Although arteries tend to be smaller in women, the arterial flow velocities are not significantly different between the sexes. PSVR is a valuable parameter in determining the degree of arterial stenosis in leg arteries. In many reports a PSVR of 2·0 was used to discriminate between a lesion with more than 50 per cent and that with less than 50 per cent reduction in diameter[3–5,10–13].

Previously, Kohler *et al.*[4] reported that duplex imaging had a sensitivity of 82 per cent and a specificity of 92 per cent, but admitted difficulty in detecting lesions distal to a critical stenosis or occluded segment. Cossman and colleagues[5] examined 84 legs and reported that duplex imaging has a sensitivity and a specificity of 87 and 99 per cent respectively. In the present study, by further retrospective assessment of the data using ROC statistics, a PSVR of 1·8 was more sensitive in identifying significant stenosis (sensitivity 98 per cent and specificity 97 per cent). Legemate *et al.*[6–9] used a PSVR of 2·5 to define a significant stenosis (sensitivity and specificity 84 and 96 per cent respectively) but reported that in some segments (femoropopliteal) a sensitivity of only 60–70 per cent was achieved.

Occasionally duplex ultrasonography is unable to differentiate between a very tight stenosis (99 per cent diameter reduction) and total occlusion. In this study five tight stenotic lesions (one iliac and four infragenicular) on IADSA reported as occluded on duplex imaging, while three tight iliac stenoses reported on duplex were occluded on IADSA. Similar observations have been reported by Legemate *et al.*[6–9] and Sensier *et al.*[14]. Duplex ultrasonography has a similar difficulty in differentiating between a tight carotid artery stenosis and occlusion[15]. In high-grade stenoses the flow velocity falls to a low level and may be undetected, unless the Doppler detecting system is adjusted correctly by the investigator.

In the present study, the reliability of duplex imaging in delineating the severity of lower limb arterial disease and its implications on the management strategy were established. Obesity and bowel gas can reduce visualization of the iliac arteries. Few studies[16,17] have investigated the efficacy of duplex imaging of infrageniculate disease (an overall sensitivity of 75 per cent and specificity of 95 per cent). In the present study the accuracy of duplex imaging was reduced compared with that of more proximal segments (sensitivity 82 per cent and specificity 99 per cent). Distal vessels are small making them difficult to identify and assess, and calcification causes further problems by reducing the Doppler signal.

Management of the ischaemic leg is a subject of great debate. Although intermittent claudication is relatively benign, about 7 per cent of patients will develop critical limb ischaemia within 1 year[18–23]. The indications for intervention vary between surgeons. For example, in this study, a 53-year-old man had right calf pain due to a 3-cm common femoral artery occlusion shown on both duplex and IADSA (claudication distance 400 yards). Two surgeons suggested no intervention while the other three recommended balloon angioplasty. The ideal lesion for balloon angioplasty is a short iliac artery stenosis rather than a long femoropopliteal occlusion. However, the precise limits of technical feasibility and success of balloon angioplasty in the hands of interventional radiologists in different anatomical situations are still matters for debate. It is not surprising that surgeons disagreed to some extent when presented with the same data, especially in the isolation of a non-clinical study when the patients were not available for clinical examination.

Some vascular surgeons make management decisions based on duplex imaging alone. Elsman *et al.*[24] reported that 36 of 100 patients underwent angioplasty without any diagnostic arteriography and in 62 patients the treatment strategy could be determined without diagnostic arteriography. The present data support this viewpoint; the accuracy of clinical decision based on duplex imaging compared with that based on IADSA was 94 per cent. This suggests that preoperative arteriography provides no additional diagnostic benefit over duplex ultrasonography. Duplex imaging is an accurate, non-invasive method for the routine assessment of lower limb arterial disease.

Management decisions can be made safely from the information provided by duplex imaging alone.

Background The role of inducible nitric oxide synthase (iNOS) in endotoxin-induced bacterial translocation was investigated by using its specific blocker aminoguanidine in 46 albino mice (25–35 g) allocated into four groups.

Methods The first group received intraperitoneal saline (control; 0·9 per cent w v^{-1} sodium chloride 1 ml kg^{-1}; $n = 6$), the second group intraperitoneal endotoxin (*Escherichia coli* lipopolysaccharide 055:B5 20 mg kg^{-1}; $n = 19$), the third group intraperitoneal aminoguanidine (20 mg kg^{-1}, 20 min before and 12 h after saline; $n = 6$) and the fourth group both endotoxin and aminoguanidine intraperitoneally ($n = 15$). Some 24 h later, the animals were anaesthetized with ether and blood samples were collected by cardiac puncture together with mesenteric lymph node (MLN), spleen and liver specimens under aseptic conditions. Specimens were then cultured to determine the presence of colony-forming units as an index of bacterial translocation.

Results No bacterial growth was detected in samples from the first and third groups. Colony-forming bacteria were found in ten of 14 MLN samples, eight of 14 spleens, four of 14 livers and three of 14 peripheral blood samples in the second group, with *E. coli* being the predominant pathogen. In contrast, in the fourth group, colony-forming bacteria were found in only three of 14 MLN samples ($P = 0{\cdot}02$ *versus* the second group), three of 14 spleens and one of 14 liver specimens. None of the values in the fourth group was significantly different from those in the saline control group.

Conclusion The inhibition of iNOS during endotoxaemia by its specific blocker aminoguanidine attenuates the incidence of bacterial translocation in mice. These results may be exploited clinically for the prophylaxis and treatment of septic states.

In contrast to significant improvements in the care of critically ill patients, septic shock still remains a leading cause of death in non-coronary intensive care units[1]. The development of multiple organ failure during the progression of this sepsis-triggered clinical entity increases the mortality rate from 30 to 100 per cent[2]. Although Gram-positive micro-organisms[3], some fungi[4], bacterial DNA or active synthetic oligonucleotides[5] can initiate the cascade of events that leads to septic shock and multiple organ failure, it is widely accepted that sepsis and its consequences are caused predominantly by Gram-negative bacteria[4,6] and their endotoxins[7]. Endotoxin is probably the primary initiator of septic shock. A large proportion of patients with non-Gram-negative sepsis have endotoxaemia[8] and 40 per cent of patients with septic shock lack any pathogenic micro-organisms in the blood or tissue[9–11]. Since the gastrointestinal tract is the main source of endotoxin[12], it is postulated that an increase in intestinal mucosal permeability, for example resulting from blunt multiple trauma[13], burn injury[14], intestinal ischaemia and reperfusion[15], food deprivation[16] or exogenously introduced endotoxin *per se*[17], may result in the pathological migration of live bacteria into the bloodstream as well as to gut-associated lymphoid structures[18]. This may lead to fatal multiple organ failure[19].

Recent studies have revealed the mechanisms of action of endotoxin[11], and nitric oxide appears to have the central role[20]. Briefly, endotoxin, together with cytokines (e.g. interleukin 1, tumour necrosis factor, interferon γ), leads to the induction of inducible nitric oxide synthase (iNOS) in the endothelium, macrophages and vascular smooth muscle cells[21]. This results in the production of copious amounts of nitric oxide[22], which renders the vasculature hyporesponsive to vasoconstrictors[23] and vasodilators[24], resulting in refractory hypotension and diminished blood flow to vital organs, which leads to multiple organ failure[25].

Aminoguanidine, a molecule containing the guanidino group of L-arginine linked to hydrazine, is reported to be a relatively selective inhibitor of iNOS. In animal experiments aminoguanidine attenuates circulatory failure and improves survival in experimentally induced Gram-negative[26] and Gram-positive[27] septic shock. It is also possible that iNOS inhibition may reduce endotoxin-induced bacterial translocation since endotoxin-induced cellular injury is closely associated with iNOS induction[28]. In addition, endotoxin-induced intestinal microvascular leakage in the small and large intestine can be blocked by iNOS inhibition[29]. On the basis of these findings, the effects of iNOS inhibition by its specific blocker aminoguanidine were studied on bacterial translocation in experimental endotoxaemia in mice.

Materials and methods

Forty-six albino mice were divided into four groups. The first group, which served as control, received intraperitoneal saline

Paper accepted 20 January 1998

(0·9 per cent w v^{-1} sodium chloride 1 ml kg^{-1}; $n = 6$); the second, intraperitoneal endotoxin (*Escherichia coli* lipopolysaccharide 055:B5 20 mg kg^{-1}; Sigma, St Louis, Missouri, USA) ($n = 19$); the third, intraperitoneal aminoguanidine (aminoguanidine hemisulphate 20 mg kg^{-1}; Sigma) 20 min before and 12 h after saline ($n = 6$); and the fourth group both intraperitoneal endotoxin and aminoguanidine ($n = 15$), complying with the relevant treatment protocols of the second and the third groups.

Twenty-four hours later, surviving animals were anaesthetized with ether, a thoracotomy was performed under aseptic conditions and blood samples were collected by sterile cardiac puncture. A 1-ml sample of blood from each animal was placed into a blood culture bottle containing brain heart infusion (BHI) broth for aerobic growth and the bottles were incubated for 7 days at 37°C. Subsequent subcultures were performed using blood agar base (Merck, Rahway, New Jersey, USA) after 48 h and eosin–methylene blue agar (EMB; Merck) after 7 days.

To obtain mesenteric lymph node (MLN), spleen and liver specimens, a midline laparotomy incision was performed. MLNs, spleen and liver were removed, weighed and homogenized in 2 ml BHI broth with grinding rods. Homogenates were placed on EMB and blood agar. After 24 and 48 h of aerobic incubation at 37°C, the plates were examined and bacteria identified using standard microbiological techniques.

All surgical interventions and preparation of the tissues were conducted under aseptic conditions with strict adherence to sterility.

Statistical evaluation was done using Fisher's exact test and differences were accepted as statistically significant when the two-tailed P value was less than 0·05.

Results

Five of 19 mice in the second (endotoxin only) group and one of 15 mice in the fourth (endotoxin plus aminoguanidine) group died within 24 h; no death was observed in the other groups. Statistical analysis indicated no significant difference in survival between the groups.

No colony-forming bacteria could be isolated from any of the samples obtained from surviving animals in the first (saline control) or the third (aminoguanidine only) group which indicated the absence of bacterial translocation in these mice (*Table 1*).

However, in the second group, colony-forming bacteria were isolated from both blood and tissue specimens. The incidence of bacteria isolated MLNs and spleen was significantly greater than that for the first group ($P = 0·01$ for MLNs and $P = 0·04$ for spleen) (*Table 1*). Although fewer colony-forming bacteria were isolated from samples obtained from the fourth group in comparison to the second, these differences were not statistically significant except for MLNs ($P = 0·02$). The predominant bacteria isolated were *E. coli*, which was present in all of the samples; *Proteus mirabilis* and diphtheroids were also encountered occasionally.

Table 1 Incidence of colony-forming bacteria as an indicator of bacterial translocation in blood and tissue specimens

	Specimen			
Group	Mesenteric lymph nodes	Spleen	Liver	Blood
Control (saline) ($n = 6$)	0	0	0	0
Endotoxin ($n = 14$)	10*	8*	4	3
Aminoguanidine ($n = 6$)	0	0	0	0
Endotoxin plus aminoguanidine ($n = 14$)	3†	3	1	0

n, Number of surviving animals after 24 h. *$P < 0·05$ *versus* control (saline) group; †$P = 0·02$ *versus* endotoxin group (Fisher's exact test)

Discussion

In this study exogenously applied endotoxin caused bacterial translocation into MLNs, spleen, liver and blood in albino mice. Aminoguanidine treatment reduced bacterial translocation. Although the differences between the values in spleen, liver and blood were not statistically significant, significant inhibition ($P = 0·02$) of bacterial translocation into the MLNs by aminoguanidine was the main finding of this study. This agrees with the concept of iNOS inhibition being beneficial in various models of septic shock[25,27].

The precise mechanism of aminoguanidine-induced inhibition of bacterial translocation is not clear. Although the selective[30] blockade of excess nitric oxide production via inhibition of iNOS[31] appears to be the main mode of action, the inhibition of polyamine catabolism[32], catalase activity[33], histamine metabolism[34] or formation of glycosylation end-products[35] may also contribute to its beneficial effects. Other possible explanations include that gastrointestinal mucosa is highly susceptible to hypoxia and ischaemia–reperfusion injury[36], and the possibility of bacteria escaping and migrating from the lumen into the bloodstream after intestinal epithelial lining disruption[2] as documented in mechanically ventilated patients[37].

In the gastrointestinal tract, endogenous nitric oxide plays an important role in the regulation of mucosal blood flow and helps mucosal protection against endotoxin-induced damage[38]. Since at least three types of nitric oxide synthase exist with diverse physiological and pathophysiological roles[39], the beneficial role of non-specific nitric oxide synthase blockage during low-perfusion states such as myocardial ischaemia[40] or septic shock[41] is questionable. By using L-arginine analogues such as N^G-nitro-L-arginine methyl ester[42] or N^G-monomethyl-L-arginine[43] during endotoxaemia, it is reported that the mortality rate is increased because of organ ischaemia and microvascular thrombosis[44]. On the other hand, there is growing evidence that selective inhibition of iNOS using aminoguanidine is beneficial by blocking the endotoxin-induced decrease in mesenteric blood flow[45], by restoring vascular responsiveness in the lungs and kidneys[46] and by inhibiting endotoxin-induced vascular leakage[47]. These reports are further supplemented by a recent study which demonstrated that aminoguanidine attenuates hepatocellular injury, respiratory dysfunction, metabolic acidosis, circulatory failure and death induced by lipoteichoic acid and peptidoglycan in an experimental model of Gram-positive shock[27]. The present results agree with current understanding of the cascade of events that lead to endotoxin-induced death and provide evidence for the attenuation of endotoxin-induced bacterial translocation by a selective iNOS blocker[48].

The concept of bacterial translocation itself remains controversial within the context of this study[49]. Despite some opposing views[50,51] there is enough evidence for its occurrence and its close association with multiple organ failure encountered during numerous states such as haemorrhagic shock[52], thermal injury[53], intestinal obstruction[54], total parenteral nutrition[55] or elective operation[56]. It is widely accepted that any injury (including exogenously applied endotoxin[17,29]) that disrupts the integrity of intestinal mucosa may facilitate the migration of bacteria out of the lumen[49] which then triggers the complex interactions between immunological defence mechanisms and invading pathogens. In the present study, the presence of colony-forming bacteria in the MLNs, spleen, liver and blood of mice that received endotoxin only is in full agreement with current understanding of the effects of endotoxin on gut-associated organ systems.

Taken together with previous results, the outcome of the present study allows a conclusion that exogenously applied *E. coli* endotoxin causes the presence of bacteria in gut-associated organs. Aminoguanidine, a relatively selective inhibitor of iNOS, attenuates this phenomenon. This action could constitute the basis for treatment of patients with systemic inflammatory response syndrome, sepsis and septic shock.

Background In patients with lymphoma, tissue for histology can be obtained through image-guided techniques or by surgery. The aim of this study was to assess the efficacy of surgical endoscopic techniques in obtaining adequate tissue specimens.

Methods Ninety-two patients with suspected or confirmed lymphoma were referred for a surgical biopsy of a deeply located intrathoracic or intra-abdominal mass or lymph node. The 86 patients who had surgery using a surgical endoscopic technique were included in this study. There were 54 men and 32 women, of mean age 34 (range 15–78) years. Most were selected directly for surgery while five previously had a failed computed tomography-guided biopsy. A total of 89 procedures were performed in 86 patients: laparoscopy (15 patients), thoracoscopy (61) and mediastinoscopy (13).

Results No patient died. One intraoperative complication occurred during thoracoscopy (1 per cent). Two postoperative complications were noted (2 per cent). Three patients required conversion to open surgery (3 per cent). Adequate tissue for histology was obtained by surgical endoscopic procedures in 87 per cent. Twelve of 13 mediastinoscopies were successful. After thoracoscopy, the success rate was 92 per cent but only nine of 15 laparoscopies were considered successful.

Conclusion In patients with lymphoma, surgical endoscopic techniques have a high diagnostic yield and a low morbidity rate. Barring exceptional circumstances these should be favoured rather than conventional open surgery.

Obtaining adequate tissue specimens is a preliminary and essential step in the diagnosis and management of patients with lymphoma. Although image-guided needle biopsies (IGNBs) have a high diagnostic yield ranging from 65 to 85 per cent[1–6], they produce insufficient specimens for specialized studies like immunophenotyping or cytogenetic analysis. The good results of IGNB reported in some large radiological series are usually presented as having an overwhelming advantage compared with the morbidity and cost of open surgery. The potential of surgical endoscopy in the diagnosis and management of lymphoma is seldom reported[7–10], so that surgical endoscopy is not yet thought as an alternative to IGNB, even in recent radiological publications[1,3].

The aim of this study was to review the efficiency of surgical endoscopic techniques in obtaining adequate specimens in patients with lymphoma, either at presentation of the disease, or at progression.

Patients and methods

Between 1991 and 1996, 92 patients presenting with suspected or confirmed lymphoma were referred for a surgical biopsy of a deeply located intrathoracic or intra-abdominal mass or lymph node (*Table 1*). Only the 86 patients who had surgery using a surgical endoscopic technique were included in this study. There were 54 men and 32 women with a mean age of 34 (range 15–78) years. Most were selected directly for surgery but five previously had a failed IGNB. During the same interval, 82 IGNBs were performed at this institution.

The different techniques used are summarized in *Table 2*. Of the six patients who had conventional open surgery, four had previous open surgery preventing laparoscopy and two needed mediastinotomy because of contraindications to split lung ventilation for thoracoscopy.

Paper accepted 8 January 1998

The indications for biopsy were as follows: for diagnosis in suspected but unproved lymphoma (48 patients); at progression of lymphoma, e.g. recurrence at a new site (23 patients); or for restaging on completion of medical treatment; in patients with a residual mass, the concern was to determine whether there was persistent disease (15 patients).

Technical aspects

Laparoscopy was initially performed with the patient supine. Reaching retroperitoneal tumours and/or latero-aortic lymph nodes was often difficult using this position, so the lateral position was adopted, which allows the intestines to drop away, facilitating the approach to the retroperitoneal vessels. Patients were discharged 1 or 2 days after surgery.

Thoracoscopy was performed using double-lumen tracheal intubation except in patients with narrowing of the trachea related to the lymphoma or a poor respiratory function contraindicating split ventilation[11,12]. In 11 patients with a small lung nodule, preoperative hook-wire localization was used[13].

Mediastinoscopy was performed using a conventional or video mediastinoscope. Whenever possible a whole lymph node was removed. Mediastinoscopy was performed either as a day case or with a single overnight stay in hospital. In the case of mediastinal tumours or lymph nodes, the indications for using either mediastinoscopy or thoracoscopy were obvious in most patients. For instance, tumours or lymph nodes in the posterior and/or inferior mediastinum could be reached only via the thoracoscope. Paratracheal lymph nodes were usually approached via mediastinoscopy. However, thoracoscopy was preferred for lesions of the upper third of the middle mediastinum, when multiple biopsies were required, such as for restaging lymphoma or biopsy of other organs, e.g. lung. Cosmetic considerations in some young women influenced choice in favour of thoracoscopy, since two or three lateral punctures are more easily hidden than a neck scar.

The study comprised 86 patients in whom 89 endoscopic procedures were performed. Clinical data, operative details and pathological results were entered prospectively into a database. A procedure was considered successful when it provided sufficient tissue for the pathologist to allow rational treatment. A small biopsy that allowed a pathological diagnosis, i.e. Hodgkin's or non-Hodgkin's lymphoma, but which did not permit subtyping was considered a partial failure. A biopsy that did not result in any diagnosis was considered a complete failure.

Results

There were no deaths. One intraoperative complication occurred during thoracoscopy (1 per cent): a pulmonary haemorrhage during lung biopsy could not be controlled thoracoscopically and required thoracotomy. The postoperative course was uneventful. Two postoperative complications were noted (2 per cent): one pleural effusion that did not need chest drainage and settled after physiotherapy and one intra-abdominal abscess following laparoscopy. In the latter case laparotomy was required but no cause for the abscess was found. It was assumed

that a pancreatic injury during laparoscopic biopsy of a peripancreatic lymph node might have caused a pancreatic fistula leading to an abscess. Indeed, pancreatic tissue was found with the lymph node sample on histology.

Three patients (3 per cent) required conversion to open surgery. As mentioned above, one patient had a thoracotomy for pulmonary haemorrhage. A second required a mediastinotomy because of inefficient lung collapse that did not permit a safe thoracoscopic examination. Finally, in the laparoscopic group, a technical problem led to the need for a laparotomy. In all these three patients, a pathological diagnosis was obtained.

The mean duration of postoperative stay was 1 (range 1–2) days after mediastinoscopy, 3 (range 1–10) days after thoracoscopy and 3 (range 2–14) days after laparoscopy.

The overall success rate of surgical endoscopic procedures was 87 per cent. Twelve of 13 mediastinoscopies were successful. The patient whose mediastinoscopy was not contributory had repeat thoracoscopy 1 month later. In the thoracoscopic group, the success rate was 92 per cent. Only nine of 15 laparoscopic procedures were successful; there were three complete failures and three partial failures, due to inadequate size of the lymph node biopsies. In total, four patients had a difficult phenotyping (partial failure). In two, no further surgery was necessary; in the other two, a repeat endoscopic procedure was performed successfully. The final histopathological subtypes of the lymphomas are listed in *Table 3*. The histological details of all failed cases are presented in *Table 4* and of patients investigated for possible residual disease in *Table 5*.

Discussion

Despite the rapid development of surgical endoscopy, laparoscopy and/or thoracoscopy are not used routinely as diagnostic and staging tools in the diagnosis and management of lymphoma. In 1993, Ribet and Cardot[14] reported a series of 480 anterior mediastinal tumours. Fifty-two were lymphomas; 32 were biopsied via mediastinotomy and five via thoracotomy or sternotomy. Laparotomy, thoracotomy and sternotomy all have the inherent morbidity of major surgery. In a series of 133 laparotomies for Hodgkin's disease, Jockovitch *et al.*[15] reported a 9·8 per cent rate of small bowel obstruction, requiring repeat laparotomy in most cases.

An alternative, less invasive biopsy technique is done using ultrasonographic or computed tomography (CT) guidance. Radiologically guided biopsies were previously performed using fine-needle aspiration cytology but this gave a pathological diagnosis in only 64 per cent of patients[6]. With core-needle biopsies, the diagnostic accuracy is around 80 per cent in many recent series, especially when several samples can be obtained using a coaxial technique[1,3]. In the series of Ben-Yehada *et al.*[1] 8 per cent of the patients received therapy on the basis of the core-needle biopsy alone. In the study of Pappa *et al.*[3] the rate was similar (83 per cent). In the latter study, the size of the samples was sufficient for phenotyping in all cases. The authors point out that they did not encounter the problem of missing large follicles, a theoretical limitation of IGNB for assessment of follicularity[2].

All failures of IGNB reported in recent papers have subsequently required an open surgical biopsy[1,2]. Since 1991, the present authors have used a surgical endoscopic technique rather than open surgery whenever possible. This policy has resulted in an indisputable advantage for patients whose biopsy was successful, because of the limited incisions and the short hospital stay. The success rates of thoracoscopy (56 of 61) and mediastinoscopy (12 of 13) found in this series are similar to those of other studies dealing with these techniques for mediastinal masses and/or lymph nodes[16–18].

Few studies of laparoscopy for biopsy of lymphomas are available[7–10]. In this study, laparoscopy yielded less than thoracoscopy or mediastinoscopy. Overlooking positive lymph nodes during laparoscopy is a limitation of the method[19,20]. In a series of 55 laparoscopies performed in 52 patients with suspicion of lymphoma, Conlon *et al.*[9] reported a diagnostic accuracy of 98·2 per cent. The high failure rate in the present series may be due to the fact that most abdominal masses or lymph nodes are referred to the radiologist for percutaneous biopsy[4]. Only patients not selected for IGBN had surgery. These patients either have a small lesion which may be difficult to reach laparoscopically, especially in the obese, or a high suspicion of Hodgkin's disease or low-grade non-Hodgkin's lymphoma. In the latter situation, examination of a whole lymph node is usually essential. Dissecting and removing a whole lymph node located in the retroperitoneum is sometimes difficult. Proximity of large vessels and/or pancreas may prompt excessive caution and lead to an inadequate biopsy[2]. Experience may also matter. Recently, it was found that adapting the patient's position to the procedure was helpful in exposing the retroperitoneum, making the operation easier and safer.

Surgical endoscopic techniques are especially beneficial for ruling out residual disease when a mass is still present after therapy. Despite imaging, it may be difficult to assess whether a residual mass is malignant. Thoracoscopic and laparoscopic techniques allow for multiple biopsies in different areas of the residual mass, thus reducing the likelihood of a false-negative diagnosis.

Based on this study, the following management may be proposed. Abdominal masses or lymph nodes of sufficient size for percutaneous biopsy[21] should be approached primarily through IGNB. When Hodgkin's disease is suspected, the need to examine a complete lymph node makes surgery preferable[4,6]. Open surgery may be avoided in most cases, although increased experience with laparoscopic biopsy is necessary to improve results still further. For patients with lymph nodes of the middle mediastinum, mediastinoscopy is the procedure of choice because of its high diagnostic yield as well as its low morbidity and short postoperative stay[12,22,23]. Patients with a lung nodule or other mediastinal mass are best investigated by thoracoscopy[12,16,18]. CT-guided biopsy is indicated for masses close to the chest wall and/or in patients with respiratory failure[5].

Background Intra-abdominal abscess remains a significant cause of morbidity following appendicectomy. In children, little emphasis has been placed on the non-invasive management of this complication using antibiotic therapy alone. This study reviews the experience of a paediatric surgical department in managing abscess arising after appendicectomy.

Methods Hospital records of all children undergoing appendicectomy between January 1992 and January 1997 were reviewed retrospectively.

Results Some 1024 children underwent appendicectomy over a 5-year period. Twenty three patients (2·2 per cent) developed abscesses after appendicectomy. Non-operative management with intravenous or oral antibiotics alone was successful in 21 patients, with complete clinical and radiological resolution of the abscess. Drainage of the septic collection was performed in only two patients: by laparotomy ($n = 1$) and by the transrectal route ($n = 1$).

Conclusion Antibiotic therapy alone is an efficacious and safe first-line treatment modality in children who develop this complication. Drainage of an abscess developing after appendicectomy is rarely necessary in children.

Acute appendicitis is the commonest emergency requiring abdominal surgery in children[1]. The recommended treatment is appendicectomy, and the management of affected children is standardized in most adult general and paediatric surgical units. Appendicectomy is uniformly associated with a low morbidity and mortality rate[2]. However, there remains a small yet significant morbidity attributed to complications following surgery.

Intra-abdominal abscess is an important cause of prolonged hospital stay or readmission following appendicectomy. The accepted treatment of this complication has followed traditional surgical philosophy which requires drainage of the abscess[1,3]. To this end, there has been a trend towards the use of minimally invasive techniques such as ultrasonographically guided drainage via the percutaneous, transvaginal or transrectal routes, reserving laparotomy for cases in which the intra-abdominal collections are not amenable to evacuation by these methods[3–6]. Although most drainage techniques employ the concomitant use of broad-spectrum antibiotics, little emphasis has been made in the literature regarding solely non-invasive management of abscess after appendicectomy with antibiotic therapy alone. In this study, recent experience in the management of this complication in children is presented.

Patients and methods

The hospital records of all children undergoing appendicectomy between January 1992 and January 1997 were reviewed. Patients who developed an intra-abdominal abscess following appendicectomy were entered into the study. Children who had an established appendiceal abscess at initial presentation were excluded from further analysis. Eligible patients were identified and the following information recorded: age, sex, clinical features, white cell count, radiological diagnosis, site and size of abscess, method of definitive treatment and outcome. The following details regarding the original appendicectomy were obtained: duration and nature of symptoms before diagnosis, operative findings, cultures of peritoneal swabs, antibiotic therapy and postoperative course.

All patients received intraoperative antibiotics, with cefotaxime and metronidazole administered intravenously. Antibiotics were administered for varying periods of time after operation depending on the operative findings and clinical course of the patient (*Table 1*). If free purulent peritoneal fluid was found at operation, limited lavage was performed with warm normal saline. It is not the authors' practice to insert peritoneal drains in these patients. All wounds were closed primarily irrespective of operative findings.

Following appendicectomy, an intra-abdominal abscess was suspected if the patient developed increasing abdominal pain, ileus, diarrhoea or persistent pyrexia. After the exclusion of other causes of postoperative pyrexia, such as wound, intravenous access site, urinary tract or respiratory infection, all patients with the above symptomatology underwent ultra-

Table 1 Operative findings and antibiotic duration at initial appendicectomy in patients with subsequent abscess

Perforated appendicitis	120	20
Total		23

Paper accepted 20 January 1998

sonography of the abdomen and pelvis. Patients developing the above symptoms/signs following discharge from hospital had similar studies performed.

Criteria for the diagnosis of an intra-abdominal abscess were a defined intraperitoneal collection on ultrasonography in combination with symptoms or signs suggestive of an abscess. The presence of leucocytosis contributed to, but did not confirm, the diagnosis of intra-abdominal abscess. If an abscess was detected, patients were treated with intravenous antibiotics (cefotaxime and metronidazole). If the abscess was diagnosed while the patient was already receiving antibiotics, additional therapy, usually in the form of an aminoglycoside (gentamicin), was added to the therapeutic regimen. Ambulatory patients with mild symptoms were treated with oral antibiotics alone, usually a combination of cephradine and metronidazole.

Response to antibiotic therapy was monitored by an improvement in clinical symptoms (resolution of abdominal pain, ileus and pyrexia) and by serial ultrasonography. Drainage of the abscess by laparotomy or via a transrectal or percutaneous route was performed if the septic collection failed to show clinical or radiological signs of resolution.

Results are expressed as mean(s.d.).

Results

Some 1024 appendicectomies were performed over a 5-year period. Of these patients, 23 (2·2 per cent) developed an abscess after appendicectomy (12 boys and 11 girls). The median age at presentation was 11·7 (range 2·3–16) years. The initial operative findings are shown in Table 1. Patients developed symptoms and/or signs suggestive of an intra-abdominal abscess at varying periods after appendicectomy, ranging from 2 to 24 days, with most patients presenting between 4 and 6 days after surgery. Thirteen of the 23 children developed an abscess in the postoperative period whilst still receiving intravenous antibiotics, while ten developed symptoms at home following discharge.

Fever (temperature above 37·5°C) ($n = 18$) was the commonest presentation, either as an isolated symptom ($n = 3$) or in combination with abdominal pain ($n = 10$), vomiting ($n = 4$) or diarrhoea ($n = 6$). Five patients presented without fever. In these children, the commonest feature was abdominal pain ($n = 5$), either alone ($n = 2$) or accompanied by vomiting ($n = 2$) or diarrhoea ($n = 1$).

The white cell count was available in 15 patients who presented with symptoms of an intra-abdominal abscess. Of these, 12 patients had a leucocytosis (18·5(5·0) $\times 10^9$ per litre), while three did not (10·5(1·4) $\times 10^9$ per litre).

The diagnosis was confirmed by ultrasonography in all cases. The abscesses were most commonly located in the rectouterine or rectovesical space ($n = 16$) with the remainder in the right iliac fossa. The largest dimension of the abscess was 5·9(2·0) cm. Peritoneal fluid cultures were available in 11 cases and the commonest offending organism was *Escherichia coli* (seven of 11 cultures). Of the two patients who underwent drainage of the abscess, pus cultures grew *E. coli* in one while the other yielded no growth.

Twenty-one of the 23 patients were treated successfully with antibiotic therapy alone. Eighteen patients required intravenous antibiotics while four children responded to oral antibiotic treatment. The duration of antibiotic treatment was 7·5(2·5) days. In these children, the temperature returned to normal in a median of 4 (range 1–10) days and median hospital stay was 8·3 (range 2–30) days. One patient (hospital stay 30 days) had an abscess in the right iliac fossa which resolved with antibiotics but developed an additional complication of a sympathetic pleural effusion. The median time to ultrasonographic resolution of the intra-abdominal collection was 18·5 (range 7–60) days (*Fig. 1*).

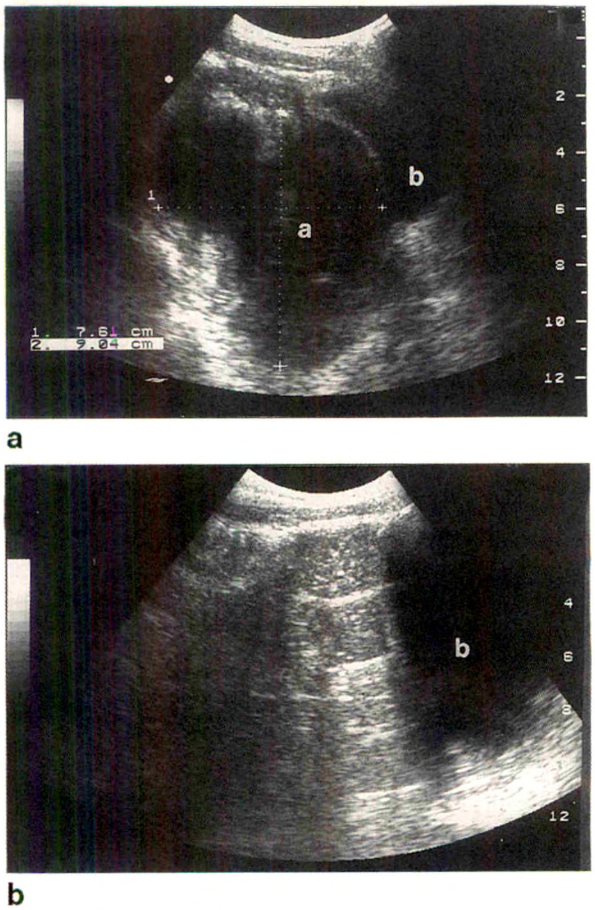

Fig. 1 **a** Ultrasonographic scan showing a large intraperitoneal abscess in the right iliac fossa. **b** Follow-up scan on the same patient showing complete resolution of the abscess after 1 week of intravenous antibiotics. a, abscess; b, urinary bladder

Non-operative treatment was not used in two patients with a pelvic abscess. One of these children underwent laparotomy and drainage as primary therapy based on the clinical condition of the child on presentation and the discretion of the attending paediatric surgeon. The other was managed successfully by ultrasonographically guided transrectal drainage. These patients were discharged 9 and 2 days respectively after drainage of the abscess.

Discussion

The routine use of prophylactic antibiotics together with improvements in the perioperative fluid management and resuscitation of children have seen a reduction in the incidence of major infectious complications following surgery for acute appendicitis[7,8]. The incidence of abscess development after appendicectomy in childhood varies from 0 to 2·2 per cent in all children with acute appendicitis[2,9,10]. The present incidence of 2·2 per cent is therefore comparable with previous reports. In children with perforated appendicitis, the reported abscess rate ranges from 0 to 6 per cent[11-13]. As expected, in the present study this complication usually followed surgery for perforated gangrenous appendicitis (20 of 23 patients). However, two patients with an inflamed appendix and one with a gangrenous appendix also developed a pelvic abscess.

The prevention of wound and/or intra-abdominal sepsis following perforated appendicitis has received a great deal of attention. Until now, the only therapeutic intervention proven to reduce the incidence of these septic complications following appendicectomy is the use of prophylactic antibiotics[8,14,15]. Peritoneal lavage with normal saline at the time of initial surgery is believed to reduce peritoneal contamination and reduce the likelihood of septic complications[7,16]. There is, however, no conclusive evidence to support the use of this procedure. The value of antibiotic lavage also remains uncertain[17,18]. The insertion of peritoneal drains at the time of operation to prevent intraperitoneal collections remains controversial and has been associated with an increase in postoperative septic complications[14,19].

In this study about half of the abscesses occurred while the patient was still receiving intravenous antibiotics. This is in agreement with an earlier report[9]. Furthermore, patients on intravenous antibiotic therapy may not manifest the classic symptoms and/or signs associated with intra-abdominal abscess. These observations enforce the need for vigilance and regular clinical monitoring in the postoperative care of these patients.

Traditional surgical doctrine dictates that pus should be drained. As a result the recommended management of the intra-abdominal abscess developing after appendicectomy is to drain or evacuate purulent collections[1-3]. Techniques for peritoneal drainage have evolved towards minimally invasive methods such as percutaneous, transrectal or transvaginal drainage under ultrasonographic or computed tomographic guidance, reserving laparotomy for instances in which these procedures are not feasible or fail[3-6]. Such procedures, although efficacious, are invasive, may require a general anaesthetic and cause significant distress and discomfort to the apprehensive child. Little emphasis exists in the literature regarding the use of antibiotic therapy alone without recourse to drainage for abscess after appendicectomy in children.

The present study has illustrated the feasibility of managing this septic complication in children largely by the sole use of antibiotics without drainage. These findings have been supported recently by a smaller study in children which reported complete resolution of the abscess in eight of ten patients with the sole use of antibiotics[9]. Notably, in the present study, intravenous antibiotics were not universally required as four patients made a satisfactory recovery on oral antibiotics alone. Neither the age nor sex of the children nor the site, size or radiological appearance of the abscess collection had any correlation with the response to non-operative therapy, demonstrating the versatility of this management policy.

In summary, this study has shown that formal drainage procedures are required only in rare circumstances in children with this postoperative complication. Treatment should be tailored to the individual patient's response with regular clinical and radiological assessment. Antibiotic therapy alone is an efficacious first-line treatment in children who develop abscess after appendicectomy.

Background Anal sphincter function is increasingly preserved following rectal excision for cancer and provides a better quality of life for patients than does a permanent colostomy. However, anastomotic complications may cause considerable morbidity and mortality. This retrospective study examined the incidence of anastomotic complications following two forms of reconstruction after resection for mid-rectal cancer: colonic pouch–anal anastomosis (CPAA) and low colorectal anastomosis (LCRA).

Methods Some 258 consecutive patients with mid-rectal cancers between 6 and 11 cm from the anal verge underwent proctectomy with mesorectal excision and either CPAA or LCRA. The incidence of clinical and radiological leaks was determined in these patients who were considered in three groups: LCRA (defunctioning stoma), LCRA (no defunctioning stoma) and CPAA (all defunctioned).

Results In the LCRA group without a defunctioning stoma, a clinical leak occurred in 17·0 per cent, compared with two of 30 in the LCRA group with a defunctioning stoma. In the CPAA group a clinical leak occurred in 4·9 per cent of patients, which was not significantly different from the rate in those with a defunctioned LCRA. Patients with a non-defunctioned LCRA were more likely to suffer a clinical anastomotic leak ($P = 0·01$), peritonitis ($P = 0·001$) and require unscheduled reoperation ($P = 0·006$) than those with a defunctioned LCRA and/or CPAA.

Conclusion The use of a protective defunctioning stoma is advocated in conjunction with LCRAs.

Recent years have seen a dramatic decrease in the frequency of abdominoperineal resection of rectal cancers in favour of sphincter-preserving procedures. Although it is generally agreed that patient satisfaction and quality of life are superior following sphincter-preserving surgery, significant morbidity and mortality do occur, with anastomotic dehiscence being the primary concern. The incidence of anastomotic leakage following anterior resection varies from 2 to 17 per cent depending on the level of the anastomosis[1], surgical expertise[2] and the method of reconstruction[3]. In the presence of generalized abdominal sepsis, mortality rates of around 50 per cent are reported[4,5] and those surviving the immediate consequences of anastomotic failure can expect a poor functional result because of stenosis and reduced compliance of the neorectum[6]. Although oncologically sound, the benefits of mesorectal excision may be associated with a high incidence of anastomotic dehiscence[7,8] and the routine use of defunctioning stomas has been suggested for these high-risk anastomoses[4].

Three approaches to reconstruction following rectal resection are available. In low rectal cancer (less than 6 cm from the anal verge) the authors routinely use colonic pouch–anal anastomosis (CPAA)[9]. For cancers in the upper rectum, above 12 cm, the lesion is resected and the distal mesorectum transected at least 5 cm below the inferior margin of the tumour followed by a low colorectal anastomosis (LCRA). The optimum reconstruction following mesorectal excision in cancers with an inferior margin falling between 6 and 11 cm is unknown and the decision between CPAA and LCRA is left to the discretion of the surgeon. This paper reports experience of anastomotic complications in a series of 258 patients with cancers between 6 and 11 cm, treated with CPAA or LCRA.

Paper accepted 27 January 1998

Patients and methods

Between July 1987 and December 1995, 398 consecutive patients underwent anterior resection for rectal cancer 12 cm or less from the anal verge. A group of 258 patients was selected with cancers situated between 6 and 11 cm from the anal verge in whom the decision to form CPAA or LCRA was made at operation. All rectal resections included the mesorectum and from 1992 total mesorectal excision (TME) with autonomic nerve preservation according to the method described by Heald and Ryall[10] was employed. In all cases the splenic flexure was mobilized and high vascular ligation was performed. Proximal descending or distal transverse colon was used for anastomosis to the rectum or anus and adequate vascularity of the colon was confirmed by identification of pulsatile blood flow on dividing a distal appendix epiploica vessel or at the marginal artery. All CPAAs were defunctioned through a loop ileostomy or colostomy but for LCRA this decision was left to the discretion of the surgeon, depending on the patient's condition, intraoperative progress and testing of the anastomosis by air insufflation. Thus, three groups were available for study: non-defunctioned LCRA, defunctioned LCRA and defunctioned CPAA.

One hundred and twenty-two patients had CPAA and 136 LCRA. The technique of CPAA has been described previously[11]. The LCRAs were either double stapled ($n = 88$) or sutured ($n = 48$); all anastomoses in the former group were tested routinely by air insufflation. In all cases, two vacuum drains were

placed in the pelvis to reduce perianastomotic collections. A defunctioning stoma was performed in all patients who had CPAA and in 30 patients with LCRA. The level of the anastomosis was calculated in patients with a LCRA by subtracting the distal resection margin from the tumour level as measured at preoperative proctoscopy. A subgroup of patients received preoperative radiotherapy determined by the presence of tumour fixation. All patients received standard bowel preparation and three doses of prophylactic antibiotics. The characteristics of all patients appear in *Table 1*.

All patients with a CPAA and those who had LCRA and a defunctioning stoma underwent water-soluble contrast enema before stoma closure, 8-10 weeks after operation. In addition, a water-soluble contrast enema was performed in any patient with features suggesting anastomotic leak. Clinical leak was defined as evidence of generalized or pelvic infection associated with symptoms such as abdominal pain, fever, leucocytosis or shock. The leakage was confirmed by contrast enema, imaging or at reoperation. Asymptomatic anastomotic leaks were identified at routine contrast studies before stoma closure and all were treated with retardation of stoma closure.

Statistical analysis

Values are given as mean(s.d.). Fisher's exact test was used to compare qualitative variables and analysis of variance for quantitative variables. $P<0·05$ was considered statistically significant.

Results

The postoperative course was free from complications in 61·2 per cent of patients (*Table 2*). The duration of hospital stay was significantly longer in the CPAA and defunctioned LCRA groups. The reported values include days spent in hospital for stoma closure and readmission for complications after discharge. Resection was considered palliative because of metastatic disease in eight patients in the defunctioned LCRA group, 16 patients in the non-defunctioned LCRA group and eight patients in the CPAA group.

In the LCRA group without a defunctioning stoma, clinical anastomotic leaks occurred in 18 of 106 patients and included nine patients with frank peritonitis, seven with pelvic abscess and/or five with rectovaginal fistula. Seventeen patients in this LCRA group required reoperation (*Table 3*). Clinical leakage in the subgroup of LCRA with a defunctioning stoma occurred in two patients, resulting in one case each of pelvic abscess and rectovaginal fistula, both managed operatively. Reoperation in this group was also required in one patient with early postoperative small bowel obstruction. An asymptomatic leak occurred in one patient, which healed on conservative management with delay in stoma closure. Seventeen per cent of stapled anastomoses required reoperation for clinical leak compared with 8 per cent of sutured anastomoses ($P=0·25$). The use of a

LCRA, low colorectal anastomosis; CPAA, colonic pouch–anal anastomosis defunctioning stoma was similar between the stapled and sutured group: 20 *versus* 25 per cent respectively ($P = 0{\cdot}69$).

In the CPAA group clinical leaks occurred in six patients and asymptomatic leaks in four. No peritonitis occurred in this group; clinical leaks presented as fever ($n = 1$), pelvic abscess ($n = 2$) and pouch vaginal fistula ($n = 3$). Four patients required further surgery (*Table 3*); the remainder responded to conservative treatment with antibiotics and delay in stoma closure. Overall, patients with non-defunctioned LCRA were significantly more likely to suffer a clinical anastomotic leak ($P = 0{\cdot}01$) and peritonitis ($P = 0{\cdot}001$) than those with a defunctioned LCRA and CPAA, and to require unscheduled reoperation than those with CPAA ($P = 0{\cdot}006$).

Two patients in the non-defunctioned LCRA group died after operation. One patient who also underwent extended right nephrectomy for renal carcinoma died on day 7 after reoperation for peritonitis due to ischaemic infarction of the left colon. The second patient died on the sixth day after operation from fulminant septic shock despite intensive medical management and early reoperation for peritonitis due also to colonic necrosis. In the CPAA group one patient with cirrhosis who had a palliative resection died on day 31 after operation from massive variceal haemorrhage.

As a consequence of septic complications, stomas were permanent in one of 30 patients in the defunctioned LCRA group and 2·8 per cent (three of 106) in the non-defunctioned LCRA group compared with 1·63 per cent (two of 122) in the CPAA group ($P = 0{\cdot}69$). Cardiac, respiratory and thrombotic complications occurred equally in CPAA and LCRA groups whether or not a defunctioning stoma was used and are not detailed in this report.

Discussion

The introduction of TME has been a major advance in the surgical strategy for rectal cancer resulting in a reduction in local recurrence without adjuvant therapy[5,7,12], but it is often associated with a high frequency of anastomotic dehiscence[7,8]. Following TME, the distal rectum is divided leaving a variable length of rectum, aiming to maintain an adequate distal resection margin of at least 2 cm of rectal wall. Such a resection potentially endangers the blood supply to the residual distal rectum and leaves a large pelvic space for the accumulation of clot and serous fluid with concomitant risk of pelvic infection. These features almost certainly contribute to the high frequency of anastomotic problems which have been described.

A recent analysis of 219 LCRAs at a median distance of 5 cm from the anal verge[1] reported an incidence of anastomotic problems similar to that of the present study. Leaks occurred in 17·4 per cent of patients and major leaks, presenting as peritonitis or pelvic abscess, in 11 per cent. Fifty seven per cent of the anastomoses were defunctioned compared with 22·0 per cent in this series, in which an overall clinical leak rate of 14·7 per cent for LCRA was observed. Six of 62 patients (10 per cent) without a defunctioning stoma in Karanjia's series[1] developed peritonitis with three deaths compared with an incidence of 8·5 per cent with two deaths in the present patients with LCRA and no defunctioning stoma. In patients with a defunctioned LCRA, the frequency of clinical leaks was 8·2 per cent in the series cited and 7 per cent (two of 30 patients) in this report. Long-term sequelae of anastomotic sepsis led to permanent stomas in 5 per cent of the patients in Karanjia's series and 2·9 per cent of those in the present series of LCRAs. Aitken[8] described an overall clinical leak rate of 14 per cent in a smaller series of TME; however, this included cancers up to 16 cm from the anal verge and the use of defunctioning stoma was not indicated.

A lower incidence of anastomotic complications following similar surgery has been reported by other groups undertaking TME for rectal cancer[5,12]. In one study there was a 2·9 per cent incidence of clinical anastomotic leak with no deaths, but this series included patients with direct coloanal anastomoses as well as low stapled anastomoses. In another study[5], an incidence of clinical leakage of 1 per cent after anterior resection with TME was reported, but over half of the patients had tumours situated between 11 and 20 cm from the anal verge so direct comparison is not possible.

Symptomatic anastomotic complications following stapled or handsewn CPAA are reported in up to 8·6 per cent of patients with or without a defunctioning stoma[3,13–15]. Although these series are small, their rates are similar to the present reported clinical leak rate of 4·9 per cent in the CPAA group, with reoperation required in 3·3 per cent of patients. These results are similar to those for defunctioned LCRAs in this series, and indeed there is little difference between CPAA and a non-defunctioned LCRA in terms of duration of hospitalization and complications. However, it is perhaps relevant that although all cancers fell between the 6 and 11 cm margin, overall CPAA was employed in the treatment of more cancers at the lower end of this spectrum, where LCRA may be more hazardous.

There are theoretical benefits in the use of CPAA over defunctioned LCRA. In CPAA the anastomosis is not compromised by the potentially poor vascularity of the distal rectum, and the volume of the colonic pouch and its mesocolon reduces the pelvic dead spaces, which in combination with adequate suction drainage should help prevent pelvic collections. In addition, recent evidence from Doppler studies indicates that vascularization of the apex of the colonic pouch is better preserved than that of terminal colon[16] supporting the concept that this region is the preferred site for anastomosis. Furthermore, the extrapelvic position of the coloanal anastomosis allows fistulas to evacuate spontaneously via the anus, thereby minimizing spread of pelvic sepsis. The required length of rectum at which a colonic pouch offers no further functional advantage over direct colorectal anastomosis is uncertain, but when LCRA follows TME, there is unlikely to be significant reservoir function.

It is apparent that unprotected LCRA carries a considerable risk of death and morbidity from anastomotic complications and, on the basis of the present series and that of others[4], it appears prudent to employ a defunctioning stoma with all high-risk LCRAs. In terms of anastomotic complications, there is little difference between CPAA (all defunctioned) and defunctioned LCRA and ultimately the choice should be directed by long-term functional outcome when the level of the tumour permits this choice.

---

Background Controversy exists about the optimal surgical resection for lower third rectal carcinoma. The aim of this retrospective study was to analyse whether the type of surgery is a significant predictor of outcome after curative surgery alone.

Methods Eighty-two consecutive patients underwent abdominoperineal rectum excision (APRE, 41 patients) or sphincter-saving operation (SSO, 41 patients) for adenocarcinoma at 3·5–7·5 cm from the anal margin. Cox proportional hazards technique with univariate and corrected (multivariate) analyses and the Kaplan–Meier life-table method were used to evaluate the data.

Results Tumour wall penetration and lymph node involvement, but not the tumour level or the type of surgery, were found to be significant predictors of outcome. The local recurrence rate at 1, 2 and 5 years was 10, 22 and 26 per cent respectively after APRE, and 5, 13 and 21 per cent after SSO. The disease-free survival rate at 1, 2 and 5 years was 85, 67 and 58 per cent respectively after APRE, and 88, 78 and 62 per cent after SSO.

Conclusion Tumour-related factors are significant predictors of outcome. The type of surgery (APRE or SSO) did not seem to be a significant variable in this non-randomized study.

Controversy surrounds the optimal curative resection for carcinoma of the lower third of the rectum. Published series on the results of abdominoperineal rectum excision (APRE) and sphincter-saving operations (SSOs) in rectal carcinoma are difficult to assess. Most authors report on cancer of the whole rectum, while others have reported only on middle and lower third rectal cancers together. For an appropriate comparison of techniques, however, only a limited part of the rectum should be studied because outcome deteriorates with decreasing distance between tumour and anal verge[1,2]. It is agreed that complete mesorectal excision and a distal margin of 2 cm are adequate to contain local cancer spread[3,4]. Strict application of the 2-cm distal margin rule, however, means that every carcinoma in the lower third of the rectum has to be treated by APRE. Indeed, if one takes into account smooth muscle shortening in the fresh, unpinned specimen of about 50 per cent of its *in situ* length and a 2–4-cm length of the anal canal in the conscious patient, the lower edge of a rectal cancer would have to be located at 6–8 cm above the anal verge for an SSO to be indicated. In clinical practice, however, this theoretical rule is not always respected.

The outcome in patients with cancer in the lower third of the rectum was therefore reviewed to identify predictors of oncological outcome and, more specifically, to evaluate whether the type of operation (APRE or SSO) is related to failure, i.e. local or distant disease recurrence.

Patients and methods

Eighty-two consecutive patients with carcinoma of the lower third of the rectum were studied. The lower third of the rectum was defined as the zone extending from the anorectal ring to 7·5 cm from the anal margin[5] and all patients underwent primary 'curative' surgery (R_0) between January 1984 and December 1993. Exclusion criteria were rectal tumours extending into the anal canal (21 patients), intraoperative tumour breach or soiling (eight patients) and perioperative adjuvant (chemo)radiation (12 patients). A sphincter-saving procedure was performed in 41 patients and an APRE in another 41. Five patients had a synchronous gastrointestinal carcinoma, two in the APRE group and three in the SSO group, treated at the time of rectal surgery. Comparative analysis showed no significant difference with regard to sex ratio, tumour diameter, depth of tumour wall penetration, lymph node involvement, tumour node metastasis (TNM) stage, differentiation grade, synchronous carcinoma and operating time between the APRE and SSO groups. Mean(s.d.) age of patients in the APRE and SSO groups was 68(10) and 60(10) years respectively $P < 0·001$, *t* test). The mean(s.d.) distance from the anal margin, measured with a rigid proctoscope, was 4·5(1·2) cm in the APRE group compared with 5·3(1·1) cm in the SSO group ($P = 0·001$, *t* test). Of four surgeons, one performed 24 of the 41 SSOs ($P < 0·001$, χ^2 test).

A sphincter-saving procedure consisted of low anterior resection (11 patients), restorative rectal excision with straight coloanal anastomosis (12) or colon pouch–anal anastomosis (18). The anastomosis was hand sewn in 22 patients and stapled in the remainder. A protective stoma was constructed in 23 patients.

The mean(s.d.) duration of hospital stay was 19·7(9·5) days after APRE and 17·7(9·2) days after SSO (*P* not significant). Postoperative complications occurred in 40 patients: in 18 of 41 after APRE and in 22 of 41 after SSO (*P* not significant). Postoperative complications after APRE were wound infection (five patients), bladder dysfunction (four), ileus (three), urinary tract infection (UTI) (two), bleeding (two), pulmonary complications (two), deep venous thrombosis (one), urethral fistula (one) and colostomy retraction (one). In the SSO group symptomatic anastomotic leakage occurred in nine patients, UTI in four, ileus in four, pulmonary complications in three, wound dehiscence in one, bladder dysfunction in one and delirium in one.

Follow-up was complete up to 31 December 1995. All patients were re-examined at 6-month intervals, including serum carcino-

---

Paper accepted 20 January 1998

embryonic antigen determination, ultrasonography of the liver and chest radiography. Colonoscopy was performed at 1 year and thereafter at 3-year intervals if normal. When a recurrence was suspected abdominal computed tomography (CT), endorectal ultrasonography (after SSO) and whole-body positron emission tomography with $[^{18}\text{F}]$fluorodeoxyglucose (since 1990) was performed. Pelvic magnetic resonance imaging and thoracic CT were performed only when suggested by the radiologist.

Time to event analyses were performed using the Cox proportional hazards technique. Individual or univariate analysis as well as corrected, multivariate analysis was performed to identify the optimally combined prognostic group of factors. The events studied were local recurrence and local or metastatic recurrent disease (disease-free survival). For each analysis the following potential prognostic variables were taken into account: age, sex, concomitant disease (yes/no), American Society of Anesthesiologists score, localization of the tumour from the anal margin, maximum tumour size, tumour differentiation grade, tumour wall penetration, lymph node involvement, TNM stage, synchronous gastrointestinal carcinoma, type of surgery (APRE or SSO), surgeon, operating time and intraoperative bleeding.

Cumulative probabilities of local recurrence or disease-free survival rates were estimated using the Kaplan–Meier life-table method. Recurrence was considered local when it was located in the pelvis, whether or not in association with distant metastatic lesions. $P \leq 0{\cdot}05$ was considered statistically significant.

Results

Individual prognostic factors significantly related to one of the events studied by univariate analysis in all 82 patients are shown in *Table 1*. Tumour wall penetration, lymph node involvement, TNM stage, tumour differentiation and intraoperative bleeding were found to be related to both events. Corrected or multivariate analyses were performed to identify the combined group of factors that best predict local recurrence or disease-free survival. Lymph node involvement was identified in both analyses, whereas tumour level or type of surgery were not selected in either of them (*Table 2*). Thus, 19 of 25 patients with lymph node involvement developed local or metastatic recurrent disease compared with 12 of 57 patients with tumour-free lymph nodes.

The incidence of local recurrence and recurrent local or distant disease was found to be comparable after APRE or SSO. The local recurrence rate at 1, 2 and 5 years was 10, 22 and 26 per cent respectively after APRE, and 5, 13 and 21 per cent after SSO. The disease-free survival rate at 1, 2 and 5 years was 85, 67 and 58 per cent respectively after APRE, and 88, 78 and 62 per cent after SSO.

Because a distal safety margin of 2 cm certainly cannot be obtained in SSO for tumours located at 3–5 cm, time to event analyses were performed in this subgroup of 55 patients. The same variables were used as for the previous analyses. Univariately significant variables were the same as for the whole group of 82 patients. Again, the type of operation was not found to be significantly related to the outcome. The following variables were found to be significant in a stepwise (multivariate) analysis (the variables are given in the order in which they were selected into the model): lymph node involvement ($P = 0{\cdot}044$), tumour wall penetration ($P = 0{\cdot}023$) and tumour differentiation ($P = 0{\cdot}03$) for local recurrence; and lymph node involvement ($P < 0{\cdot}001$), tumour wall penetration ($P = 0{\cdot}001$), synchronous gastrointestinal carcinoma ($P = 0{\cdot}002$) and concomitant disease ($P = 0{\cdot}039$) for disease-free survival. The outcomes after SSO (22 patients) and after APRE (33 patients) were comparable in this subgroup of patients. The local recurrence rate at 1, 2 and 5 years was 9, 24 and 28 per cent respectively after APRE, and 9, 18 and 23 per cent after SSO. The respective disease-free survival rates were 88, 65 and 57 per cent after APRE, and 91, 77 and 64 per cent after SSO.

Table 1 Individual or univariate analysis of factors affecting local recurrence and local or distant recurrent disease

	P	
	Local recurrence	Local or distant recurrent disease
Tumour wall penetration	0·009	< 0·001
Lymph node involvement	< 0·001	< 0·001
Intraoperative bleeding	0·027	0·03
Tumour differentiation	0·023	0·015
TNM stage	< 0·001	< 0·001

TNM, tumour node metastasis

Table 2 Corrected or multivariate stepwise analysis of factors affecting local recurrence and local or distant recurrent disease

	P	
	Local recurrence	Local or distant recurrent disease
Lymph node involvement	< 0·001	0·039
Duration of operation	0·002	
ASA score	0·031	
Tumour wall penetration		0·003
Synchronous gastrointestinal carcinoma		0·009
TNM stage		0·026

Variables are given in the order in which they were selected into the model. ASA, American Society of Anesthesiologists; TNM, tumour node metastasis

Two of eight patients who had a tumour break or soiling at the time of operation developed a local recurrence after 4 and 6 months. Tumour break was reported only in the APRE group. Twelve patients had adjuvant (chemo)-radiation, seven in the APRE and five in the SSO group. Four of them developed local recurrence with distant metastasis in two between 9 and 52 months after operation. Two others developed metastatic disease at 9 and 12 months after operation.

Discussion

The level of the tumour is still probably the most important factor influencing the type of operation in a patient with resectable low rectal cancer. It has been demonstrated that the safety margin of distal clearance can be reduced to 2 cm if taking more would jeopardize the anal sphincter. Short distal resection margins have not been significantly related to pelvic recurrence[3,4,6–8]. Of course, the distal margin, or doughnut if a stapler is used, should be tumour free as well as the lateral margins. The distal safety margin is inevitably shorter after SSO than after APRE for very low rectal cancer. For an optimal comparison of techniques, a randomized trial is required. This was not a randomized trial and a selection bias may well be present. Patients in the SSO group were younger than those in the APRE group, the tumour level was somewhat higher and one surgeon performed more restorative surgery than the others. However, the distribution of all tumour-related parameters was comparable in both APRE and SSO groups, except for the tumour level. One might argue that a bias could be introduced into the data set by virtue of the selection criteria. Therefore, the outcome of the excluded patients was analysed. Although APRE seemed to be associated with an increased risk of tumour break in this series, the final outcome of these patients did not seem to be compromised.

This study included only patients who underwent curative APRE or SSO without preoperative or postoperative (chemo)radiation for carcinoma in the lower third of the rectum. The results indicate that local tumour control as well as disease-free survival are similar after SSO and APRE. Although total mesorectal excision was performed in all patients, the local recurrence rate in this series seems fairly high, indicating and confirming the quality and limits of 'curative' surgery alone. Indeed, comparable results have been reported in other non-randomized trials comparing SSO with APRE although low and mid rectal cancer were mostly analysed together[9-13]. Local recurrence rates of 20–27 per cent have been reported even after extended lymphadenectomy for tumours at or below the peritoneal reflection[14,15]. A high local recurrence rate might be explained by a high incidence of T_3 lesions: 71 per cent (29 of 41) in the APRE and 56 per cent (23 of 41) in the SSO group.

This study confirms that tumour-related variables predict outcome. It also suggests that similar control of three-dimensional tumour and lymphatic spread can be obtained by SSO and APRE for cancer in the lower third of the rectum. Since a selection bias cannot be excluded, it should not be concluded that a SSO can safely be performed in all these patients.

Background Gunshot wounds to the kidney have been managed traditionally by surgical exploration. Concerns over increased nephrectomy rates and unnecessary explorations have placed this method under scrutiny. Selective renal exploration based on solid clinical and radiographic criteria may be a safer alternative and deserves evaluation.

Methods The medical records of 52 consecutive patients with renal gunshot wounds, who were managed between September 1994 and August 1995 by a protocol of selective exploration, were reviewed. Renal injuries were explored only if they involved the hilum or were accompanied by signs of continued bleeding. Main outcome measures were the numbers of kidneys lost, as well as the morbidity and mortality related to the management of the renal injury.

Results Three patients died from associated injuries shortly after admission. Fifteen patients suffered complications but only two had complications directly associated with the renal injury. Thirty-two patients underwent renal exploration and 17 of them required nephrectomy for major renovascular or parenchymal trauma (grade IV and V). Renal exploration was successfully avoided in the remaining 20 patients. No kidneys were lost unnecessarily as a result of this policy.

Conclusion Mandatory exploration of all gunshot wounds to the kidney is not necessary. Injuries that produce stable peripheral haematomas do not require exploration.

Most penetrating renal injuries are treated by obligatory surgical exploration[1,2]. Although small stable perirenal haematomas after stab wounds have been managed successfully without surgical intervention[3,4], most authors agree that injuries produced by bullets should be explored routinely[5,6]. However, releasing the tamponade produced by Gerota's fascia may unnecessarily increase the nephrectomy rate[7]. Despite the fact that routine proximal control of the hilar vessels is being advocated to eliminate this risk[8], this manoeuvre is not always feasible or advisable in haemodynamically unstable patients with multiple injuries.

The risk of late complications, such as haematuria, arteriovenous fistula, scarring or renal hypertension, after conservative management, has been also cited as a reason for prompt exploration[9]. However, there is no evidence that these complications are reduced by operation; on the contrary, some authors have reported on the unreliability of immediate surgery to protect against such complications[10]. Thus, a selective approach to gunshot wounds of the kidney warrants further investigation.

This study evaluated the role of selective exploration of renal gunshot wounds and assessed the clinical and radiographic criteria of such a policy.

Patients and methods

All patients with gunshot wounds to the kidney were initially included in this study. Renal injuries were diagnosed in three ways: (1) direct inspection after opening of Gerota's fascia during surgical exploration, (2) presence of Gerota's fascia penetration with renal haematoma during abdominal (but not renal) exploration, and (3) evidence of renal injury during radiographic evaluation (intravenous pyelography (IVP), computed tomography (CT), renal arteriography).

All patients were managed by a dedicated trauma team. Resuscitation was conducted according to the Advanced Trauma Life Support protocol. Patients with gunshot wounds of the abdomen were managed selectively rather than by mandatory exploration according to previously published protocols[11].

Haematuria did not constitute an indication for urgent operation, unless accompanied by peritoneal signs, haemodynamic instability or rectal bleeding. Patients with haematuria and no other findings underwent IVP and/or abdominal CT. Patients who had haematuria and were operated on for other reasons had both perirenal areas inspected, and the presence of bilateral kidneys was confirmed by palpation. In the presence of active bleeding or expanding haematoma Gerota's fascia was opened, the kidney was mobilized, the bleeding was controlled by manual pressure and the injury was evaluated. Non-expanding but large haematomas in haemodynamically stable patients were explored after central control of the renal hilum. The management of the remaining perirenal haematomas consisted of exploration of the renal hilum and proximal ureter without breaching Gerota's fascia.

Demographic data and information regarding the injury, diagnostic tests, therapeutic procedures and outcome were recorded prospectively. Renal injuries were graded according to the recommendations of the Organ Injury Scaling Committee of the American Association for the Surgery of Trauma[12]. Statistical comparisons were conducted by using the χ^2 test and Fisher's exact test.

Results

From September 1994 to August 1995, 452 patients with non-tangential gunshot wounds to the abdomen and back were admitted. Of these 54 had renal injuries. There were 50 men and four women with a mean age of 26·2 (range

Paper accepted 2 February 1998

16–50) years. The mean Injury Severity Score (ISS) was 20 (range 4–51). Associated intra-abdominal injuries were found in 48 patients, with the liver being the most commonly injured organ. Two patients died on the operating table before any assessment of their renal injuries was made and were excluded from any further analysis. Three more patients died within the first 24 h from associated injuries. No additional deaths occurred. Complications occurred in 15 patients but were associated with the renal injury in only two cases (*Table 1*). The incidence of complications among patients with nephrectomy and patients with renal repair was similar (eight *versus* five). The mean hospital stay was 16·2 (range 1–91) days.

Fig. 1 shows the treatment of the 52 patients. The type of management with regard to the grade of renal injury is shown in *Table 2*.

Patients with no laparotomy

All four patients treated non-operatively demonstrated gross haematuria but were haemodynamically stable and had no abdominal tenderness. They were monitored radiographically and in the absence of any complications were discharged voiding clear urine (*Table 3*).

Patients who had laparotomy without kidney exploration

In 16 patients renal exploration was avoided. Gross haematuria was detected in 11 patients, microscopic haematuria in two and no haematuria in three. Nine patients had preoperative investigation of the kidneys: eight by means of one-shot IVP and one by abdominal CT. The one-shot IVP showed no abnormality in six instances, decreased visualization of one kidney in one patient and suspected extravasation in the other. In the two latter patients a small lateral renal haematoma with no evidence of active extravasation was found. Abdominal CT demonstrated a grade III laceration of the upper right kidney without extravasation of contrast in a patient who also suffered significant liver trauma. This patient subsequently underwent surgery for bleeding from the hepatic wound, and underwent suture of this liver laceration and right hepatic artery ligation. The renal haematoma was not explored, and a repeat CT scan 1 month later demonstrated almost complete recovery of the right kidney.

Drainage of the injured area was performed in eight patients. No urine leaks were detected. All patients with haematuria demonstrated clear urine by the second day after operation.

One renal complication was identified in a patient who developed haematuria 1 month after the injury. CT re-

Table 2 Management according to grade of renal injury in 37 of 52 patients with gunshot wounds to the kidney

	Grade of renal injury				
	I	II	III	IV	V
Nephrectomy ($n = 17$)			1	10	6
Reconstruction ($n = 11$)		1	6	4	
Unnecessary kidney exploration ($n = 4$)	2	2			
No kidney exploration despite laparotomy ($n = 16$)*			1		
No laparotomy ($n = 4$)†		3	1		

*Only one patient was studied by computed tomography (CT); †graded according to radiographic findings on CT and intravenous pyelography

vealed lack of upper pole perfusion on the injured side. The patient underwent a successful partial nephrectomy and was discharged 7 days later with no further problems.

Patients undergoing laparotomy and kidney exploration

There were 32 patients in whom Gerota's fascia was opened.

Unnecessary explorations. In four patients exploration was conducted in violation of the protocol, as macroscopic (one patient) or microscopic (three patients) haematuria associated with small non-expanding perirenal haematomas was the sole indication for kidney dissection. Two patients had undergone a normal one-shot intravenous pyelogram before operation. Despite the presence of significant other intra-abdominal organ injuries, the kidneys were noted to have only superficial lacerations or contusions that did not require any kind of intervention.

Renal reconstructions. In 11 patients renal salvage was possible. Eight patients presented with macroscopic and three with microscopic haematuria. In six of them one-shot IVP was performed before operation but failed to show any abnormality. Partial nephrectomy was performed in four patients, debridement and suture ligation in three, packing with omentum or gelatin sponge of central holes in two, repair of the renal pelvis in one and repair of the renal vein with kidney debridement in one. One patient had a urine leak that stopped spontaneously after 12 days.

Nephrectomies. In 17 patients sacrifice of the kidney was deemed necessary. All but one of the injuries were classified as grade IV or V. Gross haematuria was present in all patients before operation. Six underwent one-shot IVP and two demonstrated poor imaging of the affected kidney. Patients who underwent nephrectomy were more often haemodynamically unstable, had more severe kidney injuries and had a higher ISS than patients who had renal reconstruction (*Table 4*).

Table 4 Comparison between patients requiring nephrectomy and patients who had renal repair after sustaining gunshot wounds to the kidney

	Patients with nephrectomy ($n = 17$)	Patients with renal repair ($n = 11$)

Discussion

Although surgical exploration has been suggested as the safest way to manage renal gunshot wounds[5], there is concern that a policy of routine exploration of all injured kidneys may result in an increased rate of nephrectomy, non-therapeutic exploration and unnecessary operative delay[4,7].

A more selective approach to renal injuries could be justified, if nephrectomy and kidney-related complication rates compared favourably to results reported after routine exploration. In this study directed patient management was based on the location and the magnitude of the renal injury. Patients with active bleeding or large haematomas were explored, whereas stable haematomas away from the hilum were left undisturbed. In cases of renal exploration, proximal vascular control was practised only in the presence of central injuries, provided that the patient was haemodynamically stable. With peripheral injuries or unstable patients the kidney was rapidly delivered to the surface and haemostasis was achieved by manual compression.

This policy resulted in 38 per cent of patients avoiding unnecessary renal exploration. There was only one late

Table 3 Findings in four patients with renal gunshot wounds who were treated non-operatively

Patient no.	Site of gunshot wound	Radiographic test	Hospital stay
1	Right upper quadrant	CT: grade II kidney laceration	6 h*
2	Right lateral abdomen	CT: grade II kidney laceration IVP: normal functioning kidney, no extravasation	1 day*
3	Left flank	CT: grade III liver laceration and grade III kidney laceration (inferior pole) IVP: normal functioning kidneys, no extravasation	2 days
4	Right flank	CT: grade II kidney laceration IVP: normal function, no extravasation	2 days

*Left against medical advice. CT, computed tomography; IVP, intravenous pyelography kidney-related complication in this group (late haematuria), which was repaired with no further sequelae for the patient. The nephrectomy rate in this series was 33 per cent, which is in accordance with the literature[5,13,14].

McAninch *et al.*[8] reported nephrectomy rates of as low as 13·8 per cent but nephrectomies were deemed necessary in 25 per cent of the more seriously injured kidneys. The present authors also performed nephrectomies almost exclusively for grade IV and V renal injuries. Unfortunately, a direct comparison between the two series is not feasible because of differences in study design and renal injury classification systems.

Preoperative one-shot intravenous pyelograms do not provide useful information other than the existence of two functioning kidneys. Of 23 studies performed (22 IVPs and one CT), there were two false-positive and ten false-negative tests. Routine one-shot IVP may produce unnecessary delays or misleading results. However, this test may be useful whenever there is reasonable doubt about the presence of a contralateral kidney (e.g. previously injured victim) and intraoperative palpation may be difficult (adhesions etc.). It should be always kept in mind that this test can be easily performed on the operating table, if deemed necessary.

Patients with haematuria who are treated non-operatively should undergo radiological imaging of the kidneys. Abdominal CT with intravenous contrast can provide valuable information on perfusion, parenchymal damage and other organs. The routine combination of IVP, CT and renal angiography for accurate injury grading, as proposed by some authors, is probably excessive from an economic standpoint[2,15].

Long-term follow-up in trauma patients is notoriously difficult and is the major limitation of this study. Only three patients with renal injuries returned to the hospital within a month to undergo further imaging tests (CT in two patients and IVP in one). In all cases improvement of the renal lesion was noticed. Twelve more were followed up by clinical examination for a mean of 14 (7–32) days after the injury. No kidney-related problems were reported by these patients. Given the problems with follow-up in this population, it is prudent to consider some type of radiographic renal evaluation before discharging patients who did not undergo renal exploration, so that adequate renal function can be ascertained.

In conclusion, this study shows that gunshot wounds to the kidney do not require mandatory exploration. Selective management, based on clinical, radiographic or intraoperative findings, is safe.

Clinical significance of clonality in thyroid nodules

H. KIM*, Z. PIAO*, C. PARK*, W. Y. CHUNG and C. S. PARK

*Departments of Surgery and *Pathology, Yonsei University College of Medicine, CPO Box 8044, Seoul, Korea*
Correspondence to: Dr C. S. Park

Background Many different neoplastic and hyperplastic thyroid diseases present with clinically apparent thyroid nodules. Clonality analysis indicates whether a nodule arises from the polyclonal proliferation of a group of cells or forms a clone from a genetically altered cell and thus provides objective information on the origin of the thyroid nodules. Clonality was studied in thyroid nodules using the polymerase chain reaction (PCR) assay in the X-linked human androgen receptor (HUMARA) gene by random X chromosome inactivation in women.

Methods DNA samples were obtained from 28 nodules in 21 women. All nodules and non-tumour thyroid tissues were fractioned selectively under a cryostat. Genomic DNA was isolated and digested with *Hha*I. PCR amplification of the HUMARA locus was performed using PCR mixtures containing [α-^{32}P]2′-deoxycytidine 5′-triphosphate. The PCR products were analysed by denaturing gel electrophoresis.

Results The HUMARA alleles were heterogenous in 18 of 21 patients. Among the 23 nodules from 18 patients, all of the eight papillary thyroid carcinomas were monoclonal. Two solitary nodules from follicular adenomas were monoclonal. Of the 13 follicular nodules from nodular goitres, ten were polyclonal and three were monoclonal. The monoclonal follicular nodules were larger in size (3·5 *versus* 2·0 cm, $P < 0.05$) and had a tendency towards more cystic changes than polyclonal nodules.

Conclusion PCR-based clonality study of thyroid nodules may help to distinguish hyperplastic from neoplastic nodules.

Nodules of the thyroid gland, both single and multiple, are common[1–5]. There is still no firm consensus on the best management of these lesions owing to the lack of adequate preoperative diagnostic techniques and pathological criteria to differentiate hyperplastic from neoplastic lesions[6–8].

Analysis of clonality in thyroid nodules would give important information on the origin of these lesions. Clonality analysis of thyroid nodules using differences in methylation of DNA in the active and inactive X chromosome demonstrated previously that most of the malignant nodules and some benign thyroid nodules were monoclonal[9–13]. However, several problems have prevented the application of these findings in a routine clinical setting. The Southern blot hybridization technique requires at least two restriction enzymes and relatively large quantities of DNA. Recently, a highly polymorphic short tandem repeat (STR) in the human androgen receptor (HUMARA) gene in the X chromosome was identified[14] and polymerase chain reaction (PCR) for non-random X chromosome inactivation using this gene was performed successfully to identify the clonality in various types of tumours[15,16]. DNA from 28 thyroid nodules was therefore subjected to PCR-based clonality assessment by using the size differences of the STR in the HUMARA allele; clonality was related to clinicopathological findings.

Patients and methods

Patients and tissue preparation

Twenty-eight thyroid nodules from 21 women who had undergone surgery for nodular thyroid disease were studied. These patients were identified prospectively and consecutively from April to June 1996 for a clonality study of thyroid nodules. Information from the notes was obtained to determine the demographics, nodule size and number. Patients ranged in age from 22 to 65 (mean 41) years and had from one to three clinically apparent nodules. Of the 28 nodules, 16 were nodular goitres, four were follicular adenomas and eight were papillary carcinomas. The central portion of each nodule was carefully dissected out and the tissue was snap-frozen in liquid nitrogen. A portion of the grossly non-tumorous thyroid tissue was sampled separately.

DNA extraction

DNA was extracted from the frozen tissue. In each tumour, the most homogeneous area with tumour cells was selected to reduce contamination by non-neoplastic inflammatory and stromal cells. The desired area of the tissue was fractionated by use of the cryostat fractionation technique[17] and digested overnight at 58°C in a buffer containing Tris 0·5 mol/l pH 8·9, ethylenediamine tetra-acetic acid (EDTA) 20 mmol/l, sodium chloride 10 mol/l, proteinase K 500 μg/ml and 1 per cent sodium dodecyl sulphate. After digestion, DNA was extracted with an equal volume of phenol/chloroform. DNA was precipitated with ethanol and resuspended at a final concentration of 10 μg/ml in a buffer containing Tris 3 mmol/l pH 7·5 and EDTA 0·3 mmol/l.

DNA digestion

A total of 2 μg of each DNA sample was digested with 5 units *Hha*I for 5 h at 37°C, and the reaction was terminated by incubating the mixture for 20 min at 65°C. DNA was then extracted with an equal volume of phenol/chloroform and precipitated with ethanol. DNA was washed with 70 per cent ethanol and resuspended in 20 μl water. An undigested aliquot of each DNA sample was retained as a control.

Polymerase chain reaction and gel electrophoresis

Oligonucleotide primers for the amplification of the HUMARA allele were made as described by Mutter *et al.*[15]. These primers

Paper accepted 20 January 1998

were designed to amplify variable numbers of trinucleotide repeat elements and several *Hha*I sites known to be methylated on the inactive, but not on the active, X chromosome[14]. The X chromosome inactivation patterns were determined by comparison of PCR products from *Hha*I-digested and undigested DNAs isolated from thyroid nodules and matched normal thyroid tissues. Amplification was performed in a 20-μl PCR mixture (Tris 10 mol/l pH 8·4, potassium chloride 50 mmol/l, oligonucleotide primer 0·3 μmol/l each, 2′-deadenosine 5′-triphosphate 0·2 mmol/l, 2′-deoxyguanosine 5′-triphosphate 0·2 mmol/l, 2′-deoxythymidine 5′-triphosphate 0·2 mmol/l, 2′-deoxycytidine 5′-triphosphate (dCTP) 5 μmol/l containing 1 μCi [α-^{32}]dCTP (NEN DuPont, Boston, Massachusetts, USA, 3000 Ci/mmol). Thermal cycling was followed as described by Mutter *et*

Table 1 Clinical and pathological characteristics of 23 thyroid nodules

Fig. 1 Examples of clonality analysis of thyroid nodules determined by polymerase chain reaction (PCR). The pattern of X chromosome inactivation by PCR amplification of the human androgen receptor (HUMARA) locus. X chromosome inactivation ratios were determined by comparing the amplified undigested or digested DNAs from normal thyroid (N, undigested DNA; Nd, *Hha*I-digested DNA) and tumour nodules (T, undigested DNA from tumour; Td, *Hha*I-digested DNA from tumour). In two papillary carcinomas (patients 1 and 7) one of the two HUMARA alleles was selectively eliminated (lanes 4, 6 and 12). In the adenomatous nodules of patient 7 (lanes 9 and 10) no elimination of HUMARA alleles was noted. Two nodular goitres (patients 10 and 16) showed polyclonality (lanes 16 and 24) or monoclonality (lanes 20 and 22) of different nodules. In the nodules of patient 16, different HUMARA alleles were eliminated in different nodules

al.[15] with minor modifications: (1) the reaction mixture was preheated at 97°C for 5 min; (2) incubation for 10 min at 85°C, during which 1·25 units Taq polymerase (GIBCO-BRL, Grand Island, New York, USA) were added to each reaction; (3) 25 cycles with prolonged denaturation consisting of 95°C for 1 min, 55°C for 45 s and 72°C for 90 s; and (4) final extension at 72°C for 5 min. After final extension, an equal volume of stop buffer (95 per cent formamide, sodium hydroxide 20 mmol/l and 0·05 per cent bromophenol blue and xylene cyanol) was added and the samples were loaded on to 7 per cent denaturing polyacrylamide gels containing urea 5·6 mol/l.

Statistical analysis

The clinical and pathological variables were cross-tabulated with the sources (monoclonal thyroid nodules and polyclonal thyroid nodules), and significance of association was determined using a χ^2 test and a non-parametric Mann–Whitney *U* test.

Results

Heterogeneity rates of the HUMARA allele

Of the 21 patients, 18 showed polymorphism at the STR of the HUMARA gene. Of the total 23 thyroid nodules from 18 patients, 13 were nodular goitres, eight were papillary carcinomas and two were follicular adenomas. A summary of data characterizing the thyroid nodules is given in *Table 1*.

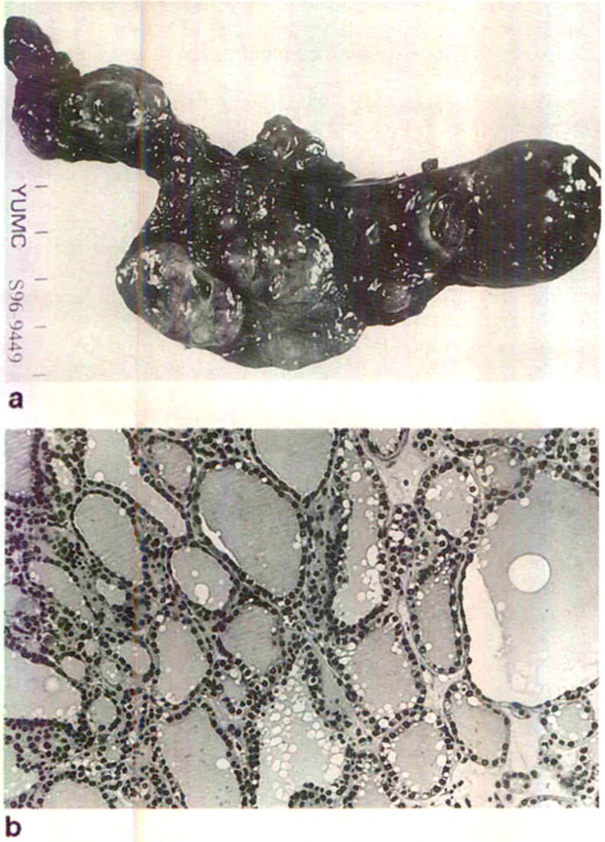

Fig. 2 **a** Gross features of a nodular goitre in patient 16. On cut section, multiple nodules were present. In the clonality assay, two nodules (right and middle) were monoclonal and the other nodule at the left was polyclonal. **b** Histopathologically, all three nodules were composed of microfollicles and macrofollicles. (Haematoxylin and eosin stain; original magnification × 100)

Clonality of the thyroid nodules

In papillary carcinomas, all of the eight nodules were monoclonal (*Fig. 1*). The two follicular adenomas were monoclonal. Of the 13 nodules from nodular goitre, ten were polyclonal and three were monoclonal. Two of the monoclonal nodules from a nodular goitre were present as separate nodules in the same patient. The X chromosome inactivation pattern of the two monoclonal nodules was different, indicating that the nodules were derived from different stem cells. The other nodule in this patient was polyclonal (*Figs 1* and *2*).

Comparison of monoclonal and polyclonal follicular thyroid nodules

Because all papillary carcinomas and follicular adenomas were monoclonal, the histological features of three monoclonal benign follicular nodules were compared with those of ten polyclonal benign follicular nodules. Monoclonal follicular nodules differed from polyclonal follicular nodules in that the monoclonal nodules were usually larger (mean 3·5 *versus* 2·0 cm, $P < 0{\cdot}05$) and had more cystic change (33·3 *versus* 20·0 per cent, $P > 0{\cdot}05$). Histologically, all of the monoclonal follicular nodules contained microfollicles; four had mixed microfollicles and normal or macrofollicles within the same lesion. In polyclonal follicular nodules, five lesions contained microfollicles.

Discussion

This study evaluated the clonality of thyroid nodules by using a PCR assay for non-random X chromosome inactivation. The HUMARA allele showed polymorphism in a high proportion of the patients with thyroid nodules and that clonality could be analysed successfully by this method. It was confirmed that malignant nodules are monoclonal and some nodules in nodular goitre are monoclonal.

It is widely accepted that tumours are monoclonal in origin[18]. Clonality analysis distinguishes monoclonal tumour nodules (nodules arising from a genetically-altered single cell and its descendants) from polyclonal hyperplastic nodules (nodules arising from the polyclonal proliferation of a group of cells)[12,19–20]. The PCR assay for non-random X chromosome inactivation has the advantage of using a small amount of genomic DNA. However, the possible disadvantage of this method is that a small amount of non-neoplastic cell contamination could provide confusing results. Studies to minimize non-neoplastic cell contamination are essential to avoid confusion or incorrect interpretation. The cryostat fractionation technique[17] seems to help in avoiding non-neoplastic cell contamination. It is also suspected that modification of PCR conditions by increasing the amount of genomic DNA and reducing the amplification cycles played a role in avoiding incorrect interpretations.

The preoperative clonality analysis of thyroid nodules using fine-needle aspiration biopsy material might provide valuable information for the clinical management of thyroid nodules. The PCR-based clonality analysis method used in this study is appropriate for the analysis of materials obtained by fine-needle aspiration biopsy because the sample is usually small. In this analysis, minimization of leucocyte contamination is essential because a large amount of blood can contaminate the biopsied samples. Recently developed microdissection and DNA extraction methods may be helpful in avoiding non-neoplastic cell contamination[21–23].

If clonality analysis using samples obtained by fine-needle aspiration biopsy could distinguish between neoplastic nodules and hyperplastic nodules before operation, the need for surgery in the management of thyroid nodules will be clearer and unnecessary operations could be avoided in patients with hyperplastic nodules.

Thyroid nodules from nodular goitre have been regarded as polyclonal, based on morphological, functional and biochemical properties[7,24–26]. However, a large proportion (33–73 per cent) of the nodules from the nodular goitre were reported as monoclonal[9–10,13,27]. These monoclonal thyroid nodules from nodular goitre present problems for pathological diagnosis because there are no objective histomorphological characteristics distinguishing monoclonal and polyclonal nodules[13,27]. Monoclonal nodules may be *de novo* neoplastic lesions or neoplasm arising in multinodular goitres. They are important because they are partially or completely unencapsulated, but further studies are needed to clarify their clinical significance. This study demonstrated that three of 13 nodules from nodular goitres were monoclonal, but the incidence was not as high as previously reported[9–10,13,27]. A study of monoclonal nodules in one patient with a nodular goitre also demonstrated that the two monoclonal nodules were formed from different progenitor cells. The clonal heterogeneity of multiple monoclonal thyroid nodules indicates that the molecular genetic events in thyroid tumorigenesis may occur in several different cells simultaneously.

Measurement of parathyroid hormone in patients with primary hyperparathyroidism undergoing first and reoperative surgery

A. BERGENFELZ, A. ISAKSSON*, P. LINDBLOM, J. WESTERDAHL and S. TIBBLIN

*Departments of Surgery and *Clinical Chemistry, Lund University Hospital, Lund, Sweden*
Correspondence to: Dr A. Bergenfelz, Department of Surgery, Lund University Hospital, S-22185 Lund, Sweden

Background The distinction between solitary parathyroid adenoma and hyperplasia can sometimes be difficult during surgery for primary hyperparathyroidism (pHPT), especially in patients who have undergone previous thyroid or parathyroid surgery. The use of intraoperative parathyroid hormone (PTH) monitoring as a possible diagnostic tool was therefore investigated.

Methods Intraoperative levels of PTH were measured in 119 patients during 121 operations (including 14 reoperations) for pHPT. The mean(s.d.) preoperative serum calcium level was 2·79(0·21) mmol/l. Blood samples were drawn before, and at 5 and 15 min after, excision of the first enlarged parathyroid gland. PTH was analysed electively in 61 patients and on-line by a modified assay for intact PTH in 48 patients. Both procedures were used in ten patients.

Results The mean(s.d.) decline in PTH concentration in 101 patients with primary exploration due to solitary adenoma was 63(17) per cent after 5 min ($n = 84$) and 83(10) per cent after 15 min. The patients with primary exploration because of multiglandular disease ($n = 6$) were correctly predicted not to have parathyroid adenoma.

Conclusion Measurement of PTH levels during surgery for pHPT is a highly sensitive method for differentiating between single and multiple gland disease. The on-line monitoring of PTH is clinically useful in patients who have undergone previous neck surgery. Its role in pHPT surgery at primary exploration should be evaluated in prospective trials.

Although surgery for primary hyperparathyroidism (pHPT) is successful in over 90 per cent of the patients[1–6], the intraoperative differential diagnosis between solitary parathyroid adenoma and hyperplasia can sometimes be difficult. In patients with previous thyroid or parathyroid surgery, the dissection should be kept to a minimum to decrease morbidity, yet render the patient normocalcaemic. A high frequency of multiglandular disease has, however, been demonstrated in patients with persistent or recurrent pHPT[7–9].

The use of intraoperative parathyroid hormone (PTH) monitoring as a possible tool to limit surgical trauma was therefore investigated.

Patients and methods

Patients

Some 119 patients operated on for sporadic pHPT were studied. There were 33 men and 86 women. The median age of the patients was 64 (range 26–88) years. The mean(s.d.) preoperative serum calcium level was 2·79(0·21) mmol/l. The mean(s.d.) preoperative serum level of intact PTH was 13(19) pmol/l. Twelve patients had slightly increased serum levels of creatinine. Seven patients had previously undergone thyroid surgery. Seven patients had persistent or recurrent pHPT. In three of these patients, one enlarged parathyroid gland, interpreted during operation as a solitary parathyroid adenoma, had been excised. Four of the patients had previously had a negative neck exploration. All patients with previous neck surgery underwent preoperative localization procedures.

Surgery

All patients were explored according to the principles of unilateral neck exploration[10]. Briefly, if the adenoma was found on the first explored side, it was excised together with the ipsilateral parathyroid gland and sent for frozen-section analysis. If the adenoma was not found on the first explored side, or the frozen-section analysis and/or intraoperative serum levels of PTH were inconclusive (see below), comprehensive bilateral exploration was performed. In patients with previous neck surgery, exploration was stopped after the first enlarged parathyroid gland was found. The wound was closed, but the patient kept under anaesthesia until the results from the frozen-section analysis and/or intraoperative serum levels of PTH were available.

Blood samples for parathyroid hormone analysis

Blood samples for PTH measurement were drawn from a peripheral vein immediately before, and 5 and 15 min after, excision of the first enlarged parathyroid gland. PTH was analysed electively in the initial 61 patients and on-line by a modified assay for intact PTH in 48 patients. In ten patients both procedures were used.

Adenoma diagnosis

The histological diagnosis of a parathyroid adenoma was made by the finding of one enlarged gland during neck exploration with histological features of adenoma (i.e. a rim of normal parathyroid tissue, chief cells with nuclear pleomorphism and decreased cytoplasmic fat content) and in most patients also by the sign of suppression in a normal-sized gland (chief cells with increased cytoplasmic fat)[11].

Since the half-life of intact PTH has been shown to be less than 5 min[12], a biochemical diagnosis of solitary parathyroid adenoma was made if serum levels of intact PTH decreased by more than 50 per cent 5 min after excision of the first enlarged parathyroid gland. The biochemical diagnosis of a parathyroid

---

Presented in abstract form to the British Association of Endocrine Surgeons, Aberdeen, UK, 14–16 May 1997
Paper accepted 5 March 1998

adenoma 15 min after gland excision was made when the PTH level decreased by at least 60 per cent as described previously[13].

Biochemical analysis

Serum levels of intact PTH were measured using the N-tact PTH assay (Incstar, Stillwater, Minnesota, USA). In this assay, two polyclonal antibodies were used. One antibody was a ^{125}I-labelled goat antibody directed to PTH_{1-34}. The other antibody was a goat antibody directed to PTH_{39-84}, which was bound to a solid phase. The sensitivity of this assay is 0·13 pmol/l and the within-assay variation of between 0·8 and 10 pmol/l is less than 4 per cent. The reference range in a normal population is 1·0–5·0 pmol/l.

To shorten the time for analysis, the assay was modified as described previously[14]. The time for incubation could thereby be reduced to 20 min, giving an interval between sampling and the assay result being available of about 30 min. The within-assay variation of between 0·8 and 10 pmol/l is less than 8 per cent for the rapid method. The correlation between the methods is 0·99.

Serum levels of calcium and creatinine were measured with an autoanalyser (Kodak Ektachem 700 × R-C; Johnson and Johnson, New York, USA).

Statistical analysis

The results are expressed as mean(s.d.) if not stated otherwise. Correlation between biochemical variables was assessed by linear regression analysis. A probability level for random difference of $P < 0.05$ was considered significant.

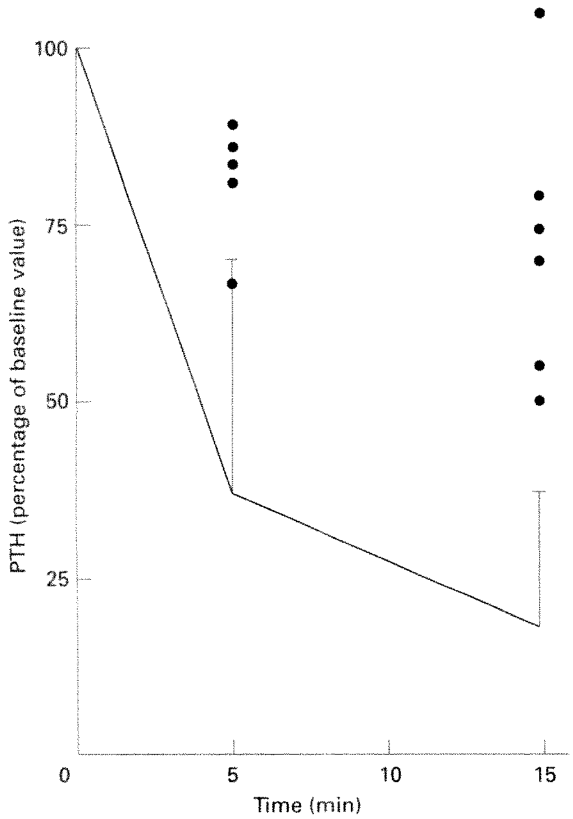

Fig. 1 Intraoperative levels of intact parathyroid hormone (PTH) in 101 patients operated on for solitary parathyroid adenoma (———) and in six patients with multiglandular disease (●) after excision of one enlarged parathyroid gland. The PTH levels were measured in 84 of the patients with adenoma and five patients with multiglandular disease at 5 min and in all 107 patients at 15 min. For the patients with solitary adenoma, values are mean(2s.d.); for patients with multiglandular disease individual values are indicated

Results

After operation all patients had normal or low calcium levels at a minimum follow-up of 1 year.

Of the 107 patients undergoing first-time exploration for pHPT, 101 had a solitary parathyroid adenoma and six patients had multiglandular disease. The median weight of the excised parathyroid adenoma in these patients was 0·75 (range 0·07–9·5) g. The mean(s.d.) decline in PTH level in the patients with primary exploration because of solitary adenoma was 63(17) per cent after 5 min and 83(10) per cent after 15 min (*Fig. 1*). With 95 per cent confidence the decrease in PTH level for patients with solitary parathyroid adenoma was at least 29 per cent from baseline value at 5 min and at least 63 per cent at 15 min. At 5 min, serum levels of intact PTH fell by more than 29 per cent in one patient with multiglandular disease. At 15 min, however, no patient with multiglandular disease had a decrease in PTH level of more than 60 per cent. At this point, the PTH level in three patients with solitary parathyroid adenoma decreased by 40, 54 and 55 per cent, and they were thus predicted not to have a solitary parathyroid adenoma. Their serum levels of calcium at the 1-year follow-up were 2·31, 2·23 and 2·21 mmol/l respectively. Using the authors' biochemical definition of a parathyroid adenoma, measurement of PTH at 5 min resulted in a sensitivity of 86 per cent, a specificity of 100 per cent and an overall accuracy of 86 per cent. At 15 min, the sensitivity was 97 per cent, the specificity 100 per cent and the overall accuracy 97 per cent.

There was no significant correlation between the preoperative serum level of total calcium and the decrease in

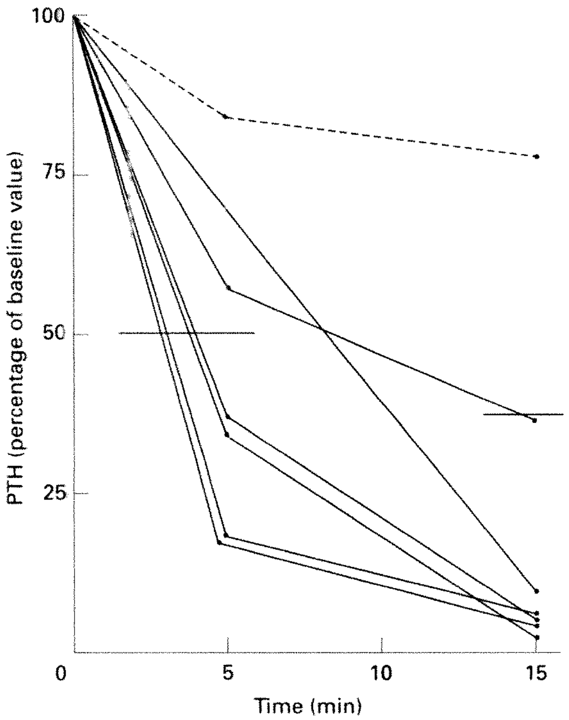

Fig. 2 Decline in intact parathyroid hormone (PTH) levels in seven patients with previous thyroid surgery at 5 and 15 min after excision of one enlarged parathyroid gland. Six patients had solitary parathyroid adenoma (———) and one patient had multiglandular disease (– – –). Bars denote the upper limit for a biochemical diagnosis of solitary parathyroid adenoma

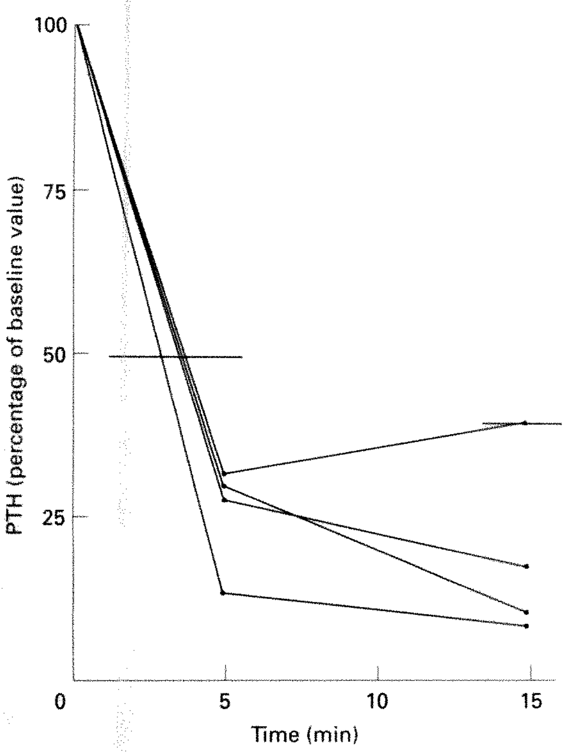

Fig. 3 Decline in intact parathyroid hormone (PTH) levels in four patients with persistent primary hyperparathyroidism with previous negative neck exploration at 5 and 15 min after excision of one enlarged parathyroid gland. Bars denote the upper limit for a biochemical diagnosis of solitary parathyroid adenoma

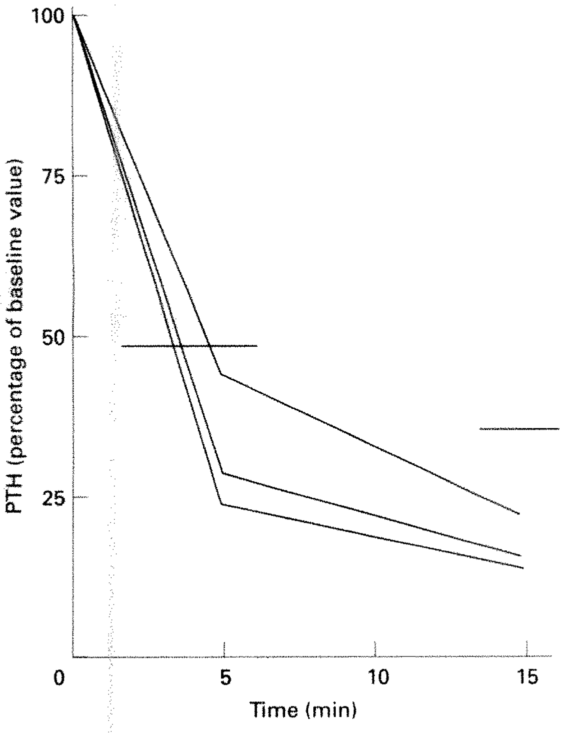

Fig. 4 Three patients with persistent or recurrent primary hyperparathyroidism with previous surgical excision of one enlarged parathyroid gland. The decrease in parathyroid hormone (PTH) levels is shown at 5 and 15 min after removal of a second enlarged gland during re-exploration. Bars denote the upper limit for a biochemical diagnosis of solitary parathyroid adenoma

intact PTH level at 5 min ($r = 0{\cdot}03$; $P = 0{\cdot}76$) and at 15 min ($r = 0{\cdot}03$; $P = 0{\cdot}74$). Eighteen (18 per cent) of the patients with solitary parathyroid adenoma had a serum level of calcium below 2·60 mmol/l (but in the high normal range) before operation. Their PTH level at 15 min after adenomectomy declined by 86(8) per cent.

There was also no correlation between preoperative serum level of intact PTH and the decrease in PTH at 5 min ($r = 0{\cdot}01$; $P = 0{\cdot}93$) and at 15 min ($r = 0{\cdot}05$; $P = 0{\cdot}68$).

In the seven patients with previous thyroid surgery, a solitary parathyroid adenoma was predicted by the decrease in PTH level in six and multiglandular disease in one patient (*Fig. 2*). After further exploration in this patient a second enlarged gland was found and removed. The decreased serum level of PTH at 5 and 15 min after removal of the second enlarged gland predicted that no hyperfunctioning tissue was left *in situ* at this point.

In the four patients who had previously undergone negative neck exploration, the decrease in PTH level after removal of the first enlarged parathyroid gland found predicted the excision of a solitary parathyroid adenoma (*Fig. 3*). In the three patients with previous excision of one enlarged parathyroid gland, removal of a second enlarged parathyroid gland during re-exploration resulted in a decrease in PTH level as for a solitary parathyroid adenoma and no further exploration was therefore performed (*Fig. 4*).

Discussion

The present investigation, based on 119 patients with pHPT, clearly shows that the intraoperative decline of intact PTH concentration is a highly sensitive and safe tool to differentiate between solitary parathyroid adenoma and multiglandular disease. The decrease in intact PTH level in patients with solitary parathyroid adenoma was, with 95 per cent confidence, at least 29 per cent from baseline value at 5 min and at least 63 per cent at 15 min.

At 5 min after gland removal the PTH level in one patient with multiglandular disease decreased by more than 29 per cent. The reason for this overlap is probably 'preanalytical'. For instance parathyroid gland manipulation, the time that it takes to draw the blood and inherent problems in determining the exact time zero could all contribute to a decreased accuracy of the test at this point. However, the biochemical definition of a solitary parathyroid adenoma (a decrease in PTH level of more than 50 per cent after 5 min and of more than 60 per cent after 15 min) provided a sensitivity of 86 per cent after 5 min and of 97 per cent after 15 min with a specificity of 100 per cent. With a decrease in PTH level of more than 50 per cent at 5 min after gland removal, the operation can therefore be terminated. In the remaining patients, the 15-min value must be awaited.

In the present investigation, no significant correlation was found between the decrease in PTH concentration and preoperative levels of serum calcium and intact PTH. In patients with solitary parathyroid adenoma and serum levels of calcium below 2·60 mmol/l (but in the high normal range) the PTH level decreased by 86(8) per cent at 15 min. The test can thus also be used reliably in patients with mild or intermittent hypercalcaemia.

The most important finding is the usefulness of the test in patients who have undergone previous neck surgery.

The intraoperative decrease in PTH level in all cases correctly predicted the return to normocalcaemia after operation.

The reliability of the test enables the surgeon to limit the surgical exploration and thereby reduce the risk of complications. In patients with persistent or recurrent pHPT and previous excision of an enlarged parathyroid gland, by definition having multiglandular disease, the decrease in PTH level after excision of a second enlarged parathyroid gland could show that no other hyperfunctioning tissue was left *in situ*.

For the rapid immunoradiometric PTH assay, the time for incubation is 20 min and the total turn-around time about 30 min. Good communication with the laboratory is therefore of utmost importance.

Recently, a immunochemiluminometric assay for rapid PTH measurement[15] has become commercially available. The incubation time for this assay is 7 min and the total turn-around time about 15 min. Since it does not suffer from the restrictions that accompany the use of radioisotopes, this assay could be used in the operating theatre.

In summary, intraoperative measurement of PTH during surgery for pHPT is a reliable method for differentiating between single and multiple gland disease as well as in patients with only mild or moderate aberrations in the serum calcium level. The on-line measurement is clearly clinically useful in patients with previous neck surgery. Its role in pHPT surgery at primary exploration, especially when performed according to the unilateral approach, needs to be evaluated in prospective randomized trials.

Background Octreotide has been shown to lower urinary calcium in primary hyperparathyroidism although the mechanism remains unclear. This study examined the effect of octreotide on parathyroid hormone (PTH) secretion from human parathyroid cells in culture and as isolated cells. Additionally *in situ* hybridization was performed for somatostatin receptor messenger RNA (mRNA) and immunocytochemistry for somatostatin in eight parathyroid adenomas.

Methods Tissue from three hyperplastic glands and three adenomas was studied as dispersed cell suspensions. Incubation was in buffers containing high (2·0 mmol/l) and low (0·5 mmol/l) calcium concentrations, with or without octreotide 200 ng/ml. Cells were also seeded into tissue culture wells for 24 h to allow receptors to regenerate. Supernatant was removed at regular intervals and PTH levels were estimated using a two-site chemiluminescent assay.

Results Mean(s.e.m.) PTH secretion at 90 min in hyperplastic cells was 445(75) pmol/l in low calcium and 160(42) pmol/l in high calcium ($P < 0\cdot02$), and in adenoma cells was 170(21) pmol/l in low calcium and 137(27) pmol/l in high calcium ($P = 0\cdot37$). There was no significant difference in secretion of PTH from cells incubated with octreotide either in culture or as dispersed cells. *In situ* hybridization failed to demonstrate any mRNA for the somatostatin receptors and no somatostatin was detected in any cells with immunocytochemistry.

Conclusion Somatostatin has no direct action on PTH production and release from human parathyroid cells and is unlikely to be of any therapeutic value in the treatment of hyperparathyroidism.

Somatostatin is a tetradecapeptide that was first isolated from hypothalamic extracts during the search for growth hormone-releasing hormone and shown to be a potent inhibitor of growth hormone secretion from the anterior pituitary[1]. It is widely distributed, being found in the central nervous system and also peripheral tissues including stomach, intestine and pancreas[2]. Somatostatin was identified initially as a product of specific hypothalamic neurones, although subsequent studies demonstrated it to be the secretory product of the δ cells of the islets of Langerhans[3,4].

Somatostatin-14 is a member of a family of somatostatin-like peptides that also includes an amino terminally extended form, somatostatin-28[5]. The two principle bioactive forms of somatostatin, somatostatin-14 and somatostatin-28, are derived by tissue-specific proteolytic processing of prosomatostatin, a 92-amino-acid precursor, and are present in varying concentrations in different tissues[6].

As well as inhibiting the release of growth hormone, somatostatin has been shown to have a powerful inhibitory action on the release of a wide variety of regulatory peptides, leading to somatostatin being referred to as 'endocrine cyanide'[7–10]. Somatostatin has also been shown to significantly reduce splanchnic circulation through selective presplanchnic vasoconstriction[11,12].

Somatostatin-14 and somatostatin-28 exert their biological effects by binding to high-affinity receptors that appear in many cases to be coupled to guanosine 5′-triphosphate-binding proteins[13,14]. Pharmacological studies using the polymerase chain reaction indicate that there are at least five subtypes of receptor named SSTRI to SSTR5[15–19].

Soon after the discovery of somatostatin it became clear that the therapeutic value would be severely impaired by the short biological half-life of 2–3 min. Octreotide is a long-acting synthetic analogue of somatostatin, being 10 000 times more active in experimental conditions, and has been shown to be of value in treating acromegaly, pancreatic fistula, carcinoid tumours and haemorrhage from oesophageal varices[20–24].

As somatostatin exhibits inhibitory effects on a wide variety of secreted hormones, several workers have studied its effect on parathyroid hormone (PTH) release. In 1976, Deftos *et al.*[25] failed to demonstrate any effect of a somatostatin infusion on PTH release from six subjects with normal parathyroid function and one patient with a parathyroid adenoma. In contrast Hargis *et al.*[26] demonstrated suppression of PTH release in rats *in vivo* when somatostatin was infused, and also from bovine parathyroid and human adenomatous parathyroid cells cultured *in vitro* with somatostatin.

In patients with primary hyperparathyroidism (HPT) octreotide has shown no significant effect on serum calcium or PTH levels. Furthermore no evidence of octreotide binding to SSTR could be demonstrated in parathyroid tissue removed at operation from the same patients. One study, however, did demonstrate a decrease in urinary calcium levels and suggested that octreotide

Paper accepted 26 January 1998

may have a place in the treatment of renal symptoms in these patients[27–29].

In light of the clinical data the current study posed three questions. (1) Does octreotide directly influence release of intact 1-84 PTH from human parathyroid cells? (2) Is the physiological ligand (somatostatin) demonstrable in parathyroid tissue? (3) Do parathyroid cells possess messenger RNA (mRNA) for somatostatin receptors? Three series of experiments were conducted. The release of intact 1-84 PTH from human parathyroid cells *in vitro* was studied, and immunocytochemistry for somatostatin and *in situ* hybridization for somatostatin receptor mRNA was performed in parathyroid tumours.

Materials and methods

Release of parathyroid hormone from human parathyroid cells

Fresh parathyroid tissue from three hyperplastic glands (removed because of secondary HPT in three different patients) and three adenomas was studied as dispersed cell suspensions.

The technique followed was originally described by Brown *et al.*[30]. Briefly, the tissue was digested with proteinase for 2 h resulting in a solution of isolated, viable parathyroid cells. The cells were resuspended in serum-free medium (DME/F12 with HEPES 15 mmol/l and L-glutamine without sodium bicarbonate; Sigma, Poole, UK) at a concentration of $2·5 \times 10^5$ per ml. The cells were then incubated in high (2·0 mmol/l) and low (0·5 mmol/l) calcium concentrations, with or without octreotide (Sandostatin; Sandoz, Basel, Switzerland) at a concentration of 200 ng/ml. Peak plasma concentration following a 50-µg subcutaneous injection is 2·25 ng/ml[31].

The theoretical possibility that the digestion processes might remove somatostatin receptors on the cell surface was controlled for by also seeding cells into tissue culture wells for 24 h to allow receptors to regenerate. Supernatant was removed at regular intervals and PTH levels were estimated using a two-site chemiluminescent assay for 1-84 intact PTH[32].

Immunocytochemistry for somatostatin in parathyroid adenomas

Wax-paraffin-embedded sections of eight parathyroid adenomas removed for primary HPT were studied. Sections of pancreas cut to display Islets of Langerhans were used as positive controls, the δ cells containing somatostatin. Serial sections from parathyroid adenoma to which primary antibody was not applied were also used to assess the degree of non-specific staining in tissue sections. A standard indirect immunocytochemistry technique was used. Washes were with phosphate-buffered saline (pH 7·2). Tissue sections were incubated with a primary mouse antisomatostatin monoclonal antibody (Sigma) for 16 h at room temperature. Following this, attached antibody was detected with an antimouse rabbit monoclonal antibody, conjugated to peroxidase (Sigma) and secondary antibody detected with the diaminobenzidine reaction. Nuclei were counterstained with haematoxylin before viewing the slides by light microscopy.

In situ *hybridization for somatostatin receptor messenger RNA in parathyroid tissue sections*

The eight adenoma samples in which immunocytochemistry for somatostatin had already been assessed were restudied. An antisense probe for detection of somatostatin receptor mRNA was selected from the complementary DNA coding sequence elucidated by Yamada *et al.*[18] and synthesized by B.B.L. (Abingdon, UK). The probe was designed to recognize the transmembrane-spanning region of the SSTRs, where the greatest homology has been found between the SSTR subtypes[33]. The 26-oligomer probe was labelled with digoxigenin according to the method of Farquharson *et al.*[34] resulting in a 5′-labelled probe: 5d′(GT CTT CAT CTT GGC ATA GCG CAG GAT)3′. Probe sequence specificity was checked through the EMBL (European Molecular Biology Laboratory) GenBank database.

Three control methods were employed. (1) Tissue known to be somatostatin receptor-positive was assessed for somatostatin receptor mRNA. The tissue was obtained from an adrenocorticotrophine hormone-producing tumour which had selectively localized with a radio-labelled octreotide scan. (2) A tissue section was included to which hybridization buffer containing no probe was applied. (3) For each tissue section examined, a second control slide of the same section was included to which an irrelevant probe was applied, antisense digoxigenin-labelled human papillomavirus 18 (HPV-18), an equimolar mixture of three 30-oligomer probes (BBL, Abingdon, UK).

Three serially sectioned slides were selected from each case and divided into two groups, test (one slide) and control (two slides). The *in situ* hybridization technique employed for mRNA staining was as described by Farquharson *et al.*[34]. Sections were incubated with hybridization buffer containing either the somatostatin receptor probe, HPV-18 probes or no probe at all. Some 20 µl of the buffer–probe mixture at a final concentration of 1·8 ng total oligonucleotide per µl was added per tissue section, which was then sealed under dimethydichlorosilane-coated cover slips. Slides were placed into a humid container for 16–18 h at 42°C. Following stringency washes, probes were detected using a conjugate mixture at room temperature for 1–2 h. Finally, the slides were washed and placed in an enzyme substrate solution in the dark for 13–15 h before the reaction was stopped by washing with distilled water several times. Slides were mounted in glycerol for viewing.

Results

Measurement of parathyroid hormone release from dispersed human parathyroid cells in culture

The results of PTH production are summarized in *Table 1* and displayed graphically in *Figs 1–3*. PTH production was significantly different at 90 min in hyperplastic cells cultured in high and low calcium concentrations ($P < 0·02$, *t* test). In adenoma cells no significant difference in PTH production was observed between different calcium concentrations ($P = 0·37$). There was no significant difference in production of PTH from either hyperplastic or adenomatous cells when incubated with octreotide either as dispersed cells or following culture.

Table 1 Parathyroid hormone secretion in tissue medium after incubation with or without octreotide

	PTH (pmol/l)	
	No octreotide	Octreotide (200 ng/ml)
Adenoma cells		
Low calcium (0·5 mmol/l)	170(21)	176(16)
High calcium (2·0 mmol/l)	137(27)	156(11)
Hyperplastic cells		
Low calcium (0·5 mmol/l)	445(75)	441(79)
High calcium (2·0 mmol/l)	160(42)	158(51)
Cultured adenoma cells		
Low calcium (0·5 mmol/l)	108(11)	103(9)
High calcium (2·0 mmol/l)	97(8)	94(10)

Values are mean(s.e.m.) concentration in tissue medium after 90 min (adenoma and hyperplastic cells) or 120 min (cultured cells) of incubation. PTH, parathyroid hormone

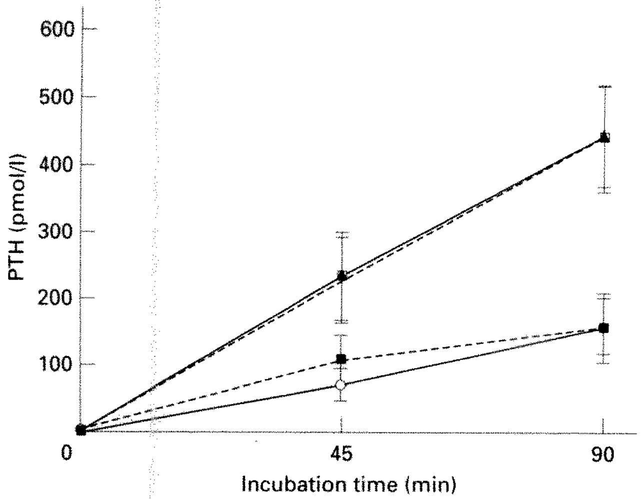

Fig. 1 Mean(s.e.m.) parathyroid hormone (PTH) production in isolated parathyroid cells from hyperplastic glands at varying concentrations of calcium ($n = 9$ per group). □, calcium 0·5 mmol/l; ○, calcium 2·0 mmol/l; ▲, calcium 0·5 mmol/l + octreotide 200 ng/ml; ■, calcium 2·0 mmol/l + octreotide 200 ng/ml

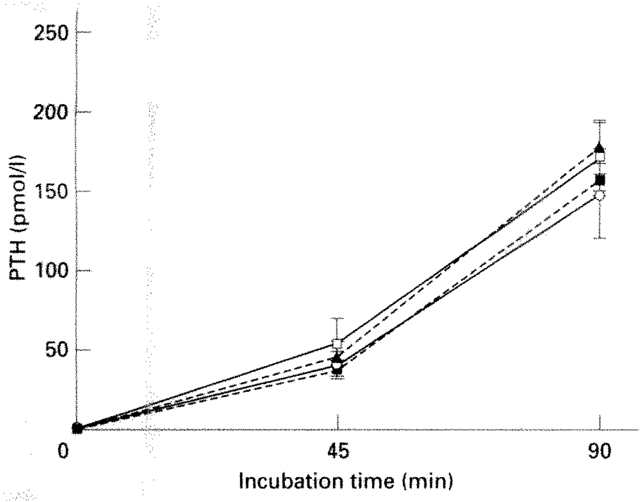

Fig. 2 Mean(s.e.m.) parathyroid hormone (PTH) in isolated parathyroid cells from adenomatous glands at various concentrations of calcium ($n = 9$ per group). □, Calcium 0·5 mmol/l; ○, calcium 2·0 mmol/l; ▲, calcium 0·5 mmol/l + octreotide 200 ng/ml; ■, calcium 2·0 mmol/l + octreotide 200 ng/ml

Immunocytochemistry for somatostatin in parathyroid adenomas

Positive immunocytochemical staining for somatostatin was clearly demonstrated in human Islets of Langerhans cells, the cytoplasm being characteristically stained brown, whilst nuclei were blue. Control sections remained clear with no evidence of any non-specific staining. None of the eight parathyroid adenomas reviewed showed evidence of either specific or non-specific immunocytochemical staining for somatostatin.

In situ *hybridization for somatostatin receptor messenger RNA in parathyroid tissue*

Positive staining of test slides compared with control slides was determined by several characteristic features: (1) granular texture of the cytoplasmic staining; (2) visible 'halo effect', i.e. no evidence of staining of the nucleus proper (nucleolar staining was ignored), with surrounding cytoplasmic staining; (3) staining confined to certain types of cell as opposed to all cell types; and (4) staining above that determined as background in control slides.

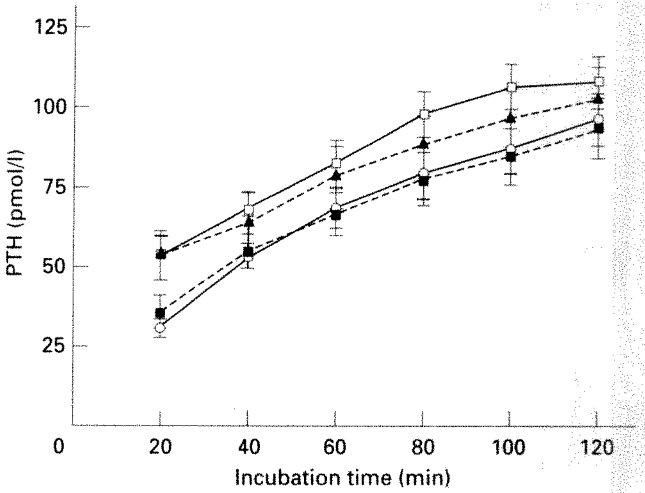

Fig. 3 Mean(s.e.m.) parathyroid hormone production in isolated parathyroid cells from adenomatous glands following culture for 24 h ($n = 9$ per group). □, Calcium 0·5 mmol/l; ○, calcium 2·0 mmol/l; ▲, calcium 0·5 mmol/l + octreotide 200 ng/ml; ■, calcium 2·0 mmol/l + octreotide 200 ng/ml

Positive staining for somatostatin receptor mRNA was clearly demonstrated in the tumour cells of the positive control specimen. There was no significant non-specific staining of mRNA by the irrelevant HPV-18 probe. Sections to which neither probe had been applied also showed no evidence of non-specific staining. None of the eight parathyroid adenomas examined showed any evidence of specific staining for somatostatin receptor mRNA or of non-specific probe binding.

Discussion

This study demonstrates that (1) octreotide has no influence on PTH secretion from either adenomatous or hyperplastic parathyroid cells maintained in culture for 24 h or as dispersed cells, (2) mRNA for somatostatin receptors is not detected in parathyroid cells and (3) immunocytochemistry for somatostatin is negative in parathyroid adenoma tissue sections.

Cells in this study obtained from parathyroid glands removed for secondary HPT maintained a degree of responsiveness to changes in external calcium concentration (*Fig. 1*). Cells obtained from adenomatous glands, however, appear to be autonomous in their function, showing no significant change in PTH release when subjected to alteration in calcium concentration of the medium (*Fig. 2*). This perhaps is to be expected when one considers the differing pathophysiology of the two conditions. Secondary HPT is a physiological response of the parathyroid glands to lowering of serum calcium from renal failure, whereas adenoma cells appear to have lost the ability to respond to changes in external calcium concentration and continue to produce PTH regardless, leading to primary HPT. It has been hypothesized that this may be due to a change in the set-point of the calcium-sensing receptor of the cell, leading to clonal proliferation and parathyroid adenoma formation in an effort to restore the calcium level to normal[35]. Neither group of cells, however, showed any change in PTH release when octreotide was added to the medium in supraphysiological doses.

By seeding cells into tissue culture wells and leaving them in complete tissue culture medium for 24 h, any somatostatin receptors stripped from the surface of the cell membrane during proteolytic digestion may, in theory, be allowed to regenerate. That adenomatous cells studied either as dispersed cells or following culture showed similar patterns of PTH secretion in high and low calcium concentrations suggests that the calcium-sensing receptor has not been stripped from the cell surface by enzymatic digestion. However, there was still no evidence of a change in PTH release when octreotide was added to the tissue medium (*Fig. 3*).

A potential flaw in this study may be that as octreotide binds only to receptor subtypes SSTR2 and SSTR5 no change in PTH secretion may be expected if parathyroid cells expressed any of the other receptor subtypes. However, all the cell culture experiments were repeated with somatostatin-14 which has a high affinity for all five SSTRs. The results are identical to those obtained with octreotide but for the sake of brevity and to avoid repetition the authors have omitted presenting the data in this paper.

Failure in this study to demonstrate the presence of somatostatin in any parathyroid tissue (none of eight tumours), suggests that the peptide is neither secreted nor absorbed by parathyroid cells. This is in contrast to other studies which have reported the presence of somatostatin-14 in 14 of 30 parathyroid adenomas and also the presence of a somatostatin-like immunoreactivity. The technique used, however, did not exclude the possibility that the somatostatin may not be localized in the parathyroid cells themselves but in the parathyroid nerves or blood vessels[36,37].

The area of greatest homology between the SSTRs is found in the transmembrane region, with greatest homology being noted between subtypes SSTR1 and SSTR4 on the one hand and subtypes SSTR2, 3 and 5 on the other. For this reason the *in situ* hybridization probe used in this study was designed to recognize a mRNA base sequence expressed in the transmembrane portion of SSTRs. No staining was demonstrated, however, for any SSTR mRNA in any of the eight adenomas studied. The lack of suitable surface receptors in parathyroid tissue strongly suggests that somatostatin plays no regulatory role in the secretion of PTH.

Administration of octreotide has been shown to have no effect on plasma levels of PTH *in vivo* either in healthy human volunteers or in those suffering from primary HPT[27–29,38]. Octreotide has, however, been shown to reduce urinary calcium in patients with primary HPT also with no observable effect on plasma PTH levels[27]. Similarly, reduced urinary calcium excretion and production of a positive calcium balance in patients with Duchenne muscular dystrophy has also been demonstrated. In these circumstances octreotide might act through somatostatin receptors known to be located in bone cells rather than by any direct action of somatostatin on the parathyroid glands[39].

In conclusion, the present study demonstrates that octreotide has no direct action on PTH release in patients with HPT and is therefore unlikely to offer any significant role in the treatment of this condition. Octreotide may have a possible role to play in the alleviation of some of the renal symptoms associated with HPT, although the effects appear to be of a secondary nature. Surgery will undoubtedly continue for the present to be the mainstay of treatment in HPT.

Background It has been suggested that p53 plays an important part in gastric carcinogenesis but the data remain inconclusive.

Methods Alteration of the tumour suppressor gene *p53* was prospectively investigated by immunohistochemistry in 168 primary gastric cancers.

Results Positive staining, indicative of gene mutations, was detected in 34 tumours (20·2 per cent). No correlation was observed between expression of p53 and various clinicopathological factors, including age, sex, tumour site, gross type, tumour size, depth of invasion, lymph node metastases, distant metastases, and tumour node metastasis stage. However, p53 overexpression was different between intestinal and diffuse type gastric cancer. Survival analysis revealed a significant survival disadvantage of p53 expression in diffuse type gastric cancer ($P = 0{\cdot}039$) but not in the intestinal type. Multivariate analysis of all 168 patients revealed that independent predictors of recurrent disease included age, invasion depth and nodal involvement but not p53 expression.

Conclusion The presence of p53 overexpression may identify a subset of more aggressive tumours with a poor prognosis in diffuse type gastric cancer.

It has been suggested that the most common genetic alternation in human cancers involves the loss of inhibitory function of the *p53* tumour suppressor gene product[1]. The *p53* gene mapped on chromosome 17p is an important negative regulator of normal cell growth and division. A common mechanism for this change appears to be the loss of one normal *p53* allele and point mutation of the remaining *p53* allele[2]. The resultant effect of these genetic alternations on intracellular p53 is a paradoxical increase in protein levels, since mutated p53 has a much longer half-life than normal p53. Accordingly, detectable levels of p53 protein product by immunohistochemistry suggest the existence of genetic alternations at this locus, since the very low steady-state levels of the normal protein (due to its rapid turnover) are usually invisible by this method[3]. Mutation of p53 and a raised protein level as determined by immunohistochemistry has been described in different types of human cancer[4–6].

Gastric cancer is a common disease worldwide and the third leading cause of cancer death in Taiwan[7]. Although aggressive surgical resection has improved the overall outcome of patients with this carcinoma, results of surgical resection for advanced cancer are still poor[8]. To search for predictors of disease survival and response to therapy is therefore mandatory. The molecular events leading to the development of gastric cancer are largely unknown, but there is now enough evidence to suggest that the functional inactivation of the *p53* gene through allelic loss and point mutation plays an important part[8–12]. Furthermore, several studies have shown recently that p53 mutations are likely to be associated with tumour metastases, stage and clinical outcome in breast cancer[13–16].

The aim of the present study was to determine whether p53 status in patients with gastric cancer patients who have undergone gastrectomy correlates with various clinicopathological characteristics and survival.

Paper accepted 6 November 1997

Patients and methods

Patients

Between July 1992 and December 1994, 168 patients who had undergone gastric resection for primary gastric adenocarcinoma were studied. No patient had undergone previous chemotherapy or radiotherapy and all patients were followed clinically for a median of 4 years. All the clinicopathological data were collected prospectively and registered in a database. The operation was performed according to the guidelines of the Japanese Research Society for Gastric Cancer[17]. Radical lymph node dissection ($R_{2/3}$) was performed routinely. A detailed histopathological examination was performed to determine the depth of invasion on the gastric wall and the extent of metastases within regional lymph nodes. The clinical stage was determined by the tumour node metastasis (TNM) system[18]. The histological diagnosis was made according to the classification of Laurén[19].

Immunohistological staining

Cancer and normal mucosa samples were taken immediately after surgical excision and snap frozen, then stored at − 70°C until use. For immunohistochemical demonstration of the p53 protein, sections of the freshly frozen tissues were cut at 6 µm and stained with specific monoclonal p53 antibody (Oncogene Science, New York, USA) by an avidin–biotin complex peroxidase complex method. Cryosat sections of 5–7 µm were cut and mounted on glass slides, then treated with 3 per cent hydrogen peroxide in methanol at room temperature for 30 min to block endogenous peroxidase. The tissue sections were then incubated for 20 min with normal non-immune goat serum from the same species as the secondary antibody. Excessive normal goat serum was blotted from the slides before incubation with the primary antibody. Sections were incubated with primary mouse monoclonal antibody against p53 gene product (Oncogene Science) at

1:50 dilution overnight in a moist chamber at 4°C. Sequentially, the sections were incubated with biotinylated goat antimouse antibody for 30 min at room temperature and peroxidase-conjugated streptavidin was applied for 10 min at room temperature. Tissue sections were then stained with 0·05 per cent 3′,3 diaminobenzidine tetrachloride freshly prepared in 0·05 mol/l Tris-hydrochloride (pH 7·6) containing 0·01 per cent hydrogen peroxide and checked by light microscopy to determine the colour of chromogen. Finally, sections were counterstained with Mayer's haematoxylin, or methyl green, and then mounted. The reaction was considered as positive when a strong colouration of the cell nucleus was evident. Negative control sections were processed immunohistochemically without the primary antibody and positive control sections were from a breast cancer known to express high levels of p53.

Statistical analysis

Data were analysed using the χ^2 test with Yates' correction and Student's t test to evaluate the statistical significance of the relationship between staging and other histopathological factors. Cumulative survival rates were calculated using the Kaplan–Meier method. Statistical differences between two survival curves were evaluated using the generalized Wilcoxon test and savage test. Multivariate analysis, Cox model of proportional hazards regression, was used to incorporate all of the explanatory variables with the greatest prognostic value[20]. $P < 0·05$ was considered to be statistically significant. The analysis was done using the Biomedical statistical package (BMDP Statistical Software, Los Angeles, California, USA).

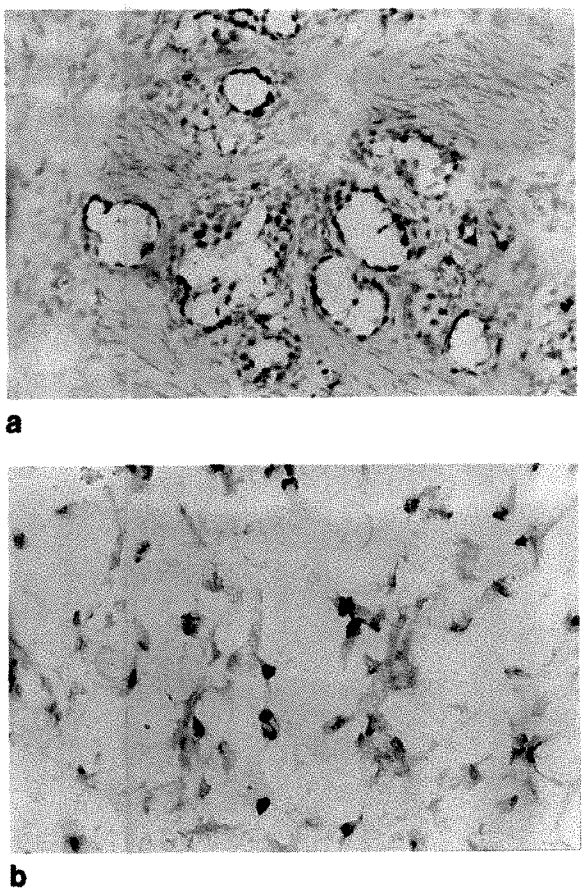

Fig. 1 Immunohistochemical staining of p53 protein in gastric cancer using monoclonal antibody. **a** Intestinal type cancer; p53 protein expression is seen primarily on cell nucleus (original magnification ×200). **b** Diffuse type cancer; cell nucleus staining is exhibited (original magnification ×400)

Results

Overexpression of p53

Nuclear staining of tumour cells was considered a positive p53 overexpression (*Fig. 1*). Nuclear positivity was not seen in any of the ten specimens of normal gastric mucosa used as controls or in the non-cancerous mucosa adjacent to the carcinoma.

An overall positive staining was seen in 34 (20·2 per cent) of 168 gastric cancers. The clinicopathological data relating to the resected tumours in both groups are summarized in *Table 1*. There was no significant correlation between p53 protein expression and any of the clinicopathological variables, including age, sex, tumour location, gross type, histological type, depth of invasion, lymph node metastases, distant metastases and TNM stage. Although p53 expression tended to be associated

T_1 3 of 23	3 of 12	0 of 11
T_2 6 of 38	5 of 20	1 of 18
T_3 21 of 80	10 of 36	11 of 45
T_4 2 of 14	0 of 4	2 of 10

with advanced rather than early cancer (21·4 *versus* 13 per cent) and intestinal than diffuse cancer (25 *versus* 17 per cent), this had no statistical significance. A significant difference was found in the timing of p53 overexpression between the intestinal and diffuse type tumours; p53 expression was found in the early stage of intestinal type tumour but only in the late stage of diffuse type tumours (*Table 2*).

Prognostic relevance

Fig. 2a shows the survival curves of both groups after gastric resection. The survival rate of patients who had p53-positive tumours was lower than that of patients with p53-negative tumours but the difference was not statistically significant ($P = 0{\cdot}400$). The survival of 83 patients with diffuse type adenocarcinomas was analysed separately; a significant difference in survival was seen between patients with p53-positive and p53-negative tumours ($P < 0{\cdot}05$) (*Fig. 2b*). However, the presence of p53 was not a significant prognostic indicator in 72 patients with intestinal type cancer (*Fig. 2c*).

Multivariate analysis of all 168 patients revealed that age, invasion depth and nodal involvement but not p53 expression were independent prognostic variables. Multivariate analysis in 83 patients with diffuse type cancer revealed that only invasion depth was an independent and significant variable.

Discussion

Immunohistochemical techniques have revealed the presence of p53 protein in between 13·3 and 67 per cent of gastric carcinomas[21–32]. The rate of immunostaining for p53 in this study (20·2 per cent) was consistent with the rates of positivity mentioned above. The wide variation in the reported incidence of p53 immunostaining may be due to the various antibodies used in different reports and the difficulty of assessing specimens with low p53 expression. The incidence of p53 abnormalities appears to differ based on the histological type of cancer in previous studies. The present study also showed a higher percentage of p53 expression for intestinal type than diffuse type lesions, the difference was not significant. However, a significant difference in the timing of p53 overexpression between Laurén histological type was observed in this study as well as others[31,32]. This result implicates different carcinogenesis processes between these two types of gastric cancer.

In addition to epidemiological and pathological studies, recent reports have shown that intestinal type and diffuse type gastric cancer are two disease entities with different carcinogenic molecular events[33,34]. Intestinal type cancer, similar to colonic cancer, arises from the progression of

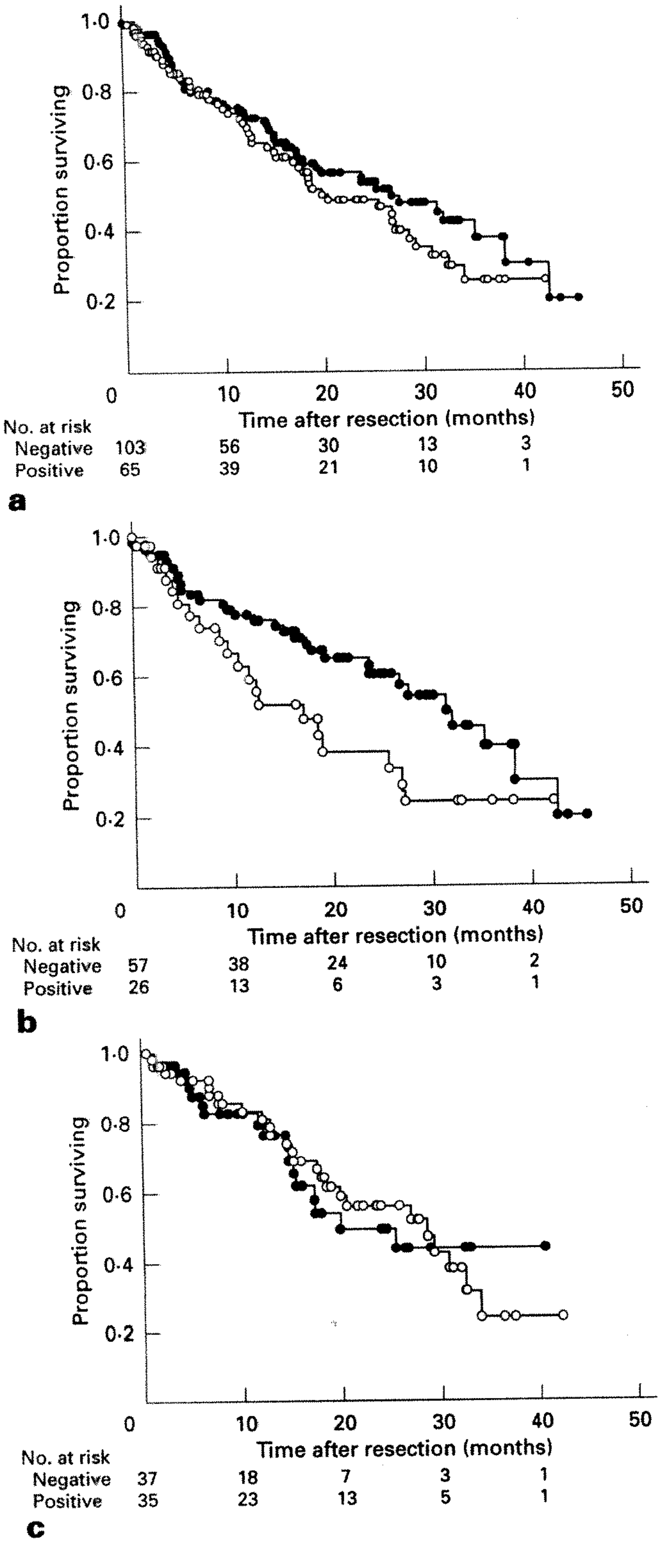

Fig. 2 Survival of patients after resection of gastric cancer. Cumulative survival curves were constructed for patients with p53-positive (○) or -negative (●) gastric carcinomas by the Kaplan–Meier method. **a** All 168 patients $P = 0{\cdot}400$ (generalized Wilcoxon test); $P = 0{\cdot}039$ (generalized savage test). **b** Eighty-three patients with diffuse type cancers. $P = 0{\cdot}045$ (generalized Wilcoxon test); $P = 0{\cdot}039$ (generalized savage test). **c** Seventy-two patients with intestinal type cancer. $P = 0{\cdot}66$ (generalized Wilcoxon test); $P = 0{\cdot}89$ (generalized savage test)

chronic atrophic gastritis, intestinal metaplasia and severe dysplasia. p53 mutations can be demonstrated in premalignant stages and early cancer of intestinal type cancer implying that alterations in p53 are not confined to the late stage for this subtype[25,30]. In diffuse type cancer, regarded as a kind of *de novo* cancer, p53 oncoprotein occurs in the late stage favouring cancer progression and metastases. Kakeji *et al.*[24] have reported that gastric cancer with p53 overexpression has a high potential for metastasizing to lymph nodes[24]. In the present study, there was no significant association between overexpression of p53 and lymph node metastases. However, that most metastatic lesions show positive p53 staining, even in patients with negative staining in primary tumours, corroborates with the finding of Kakaji *et al.*[24]. This could be explained by either a sampling error that might miss the mutation at the primary tumour site or by post-metastatic clinical divergence.

As for prognostic and p53 stainability, many reports have shown that p53 expression can serve as an independent prognostic indicator in the case of breast cancer[13–16]. Evidence for the prognostic relevance of p53 overexpression and gastric cancer is conflicting. Some authors have reported that their p53-positive cases behave more aggressively and have a worse prognosis[22,23,29], but conflicting data exist[26,27]. However, the prognostic relevance has not been compared between different histological types in previous reports and rarely by multivariate analysis. The present report shows that p53 overexpression is associated with significantly poorer survival in patients with diffuse type gastric cancer, suggesting that p53 expression identifies diffuse type carcinomas with a more malignant phenotype. Because multivariate analysis does not reveal p53 expression as an independent prognostic factor, the poorer prognosis for those with tumour expressing p53 may be attributed to a more advanced stage. In contrast, intestinal type gastric cancers are more frequently associated with p53 overexpression but without prognostic relevance. These carcinomas may use another mechanism for tumour progression, such as additional activated oncogenes or deletion of tumour suppressor genes. However, most of the patients present had advanced gastric cancer; p53 expression may still play a significant prognostic role in early gastric cancer when a large number of early cancers are analysed[35,36].

Identification of patients who have resectable high-risk disease is being increasingly taken into account by surgeons and oncologists. A large number of tumour biology-related factors have been investigated, but most have been evaluated retrospectively in paraffin-embedded material. It has been stressed that each factor that is supposed to have an impact on prognosis should be tested prospectively following curative resection in a multivariate analysis. This study evaluated the impact of a single biological factor on overall survival of gastric cancer. Further studies of other potential biological prognostic factors for gastric cancer following curative resection are indicated.

Because intestinal type and diffuse type gastric cancers may be regarded as two disease entities with different carcinogenic processes, it is possible that various biological indicators of tumour aggressiveness may play a different role in predicting the outcome of patients with these two types of gastric cancer[37,38]. It has been found that the ability of c-erbB-2 expression to predict survival is different between well differentiated and poorly differentiated gastric cancers[35]. The present study reveals that p53 expression is a prognostic indication of survival after complete resection of diffuse type gastric cancer but not in intestinal type cancer. In investigating the prognostic relevance of a new biological indicator it is mandatory to analyse these two types of gastric cancer separately.

Background This study evaluates the efficiency and safety of two methods of chest drainage after uncomplicated oesophagectomy.

Methods A prospective randomized study between active suction drainage and passive chest drainage was carried out in 101 patients who underwent gastric pull-up oesophagectomy.

Results No difference in the prevalence of pneumothorax during treatment was noted between the active (nine of 55) and the passive (four of 46) drainage groups ($P = 0{\cdot}20$). Nor was there any difference in the size ($P = 0{\cdot}46$) and duration ($P = 0{\cdot}53$) of the pneumothorax. There was no significant difference in right ($P = 0{\cdot}84$) and left ($P = 0{\cdot}61$) basal atelectases and the amounts of right ($P = 0{\cdot}10$) and left ($P = 0{\cdot}24$) pleural effusions. There were significantly more basal atelectases ($P < 0{\cdot}001$) and pleural effusions ($P < 0{\cdot}001$) in the non-operated left side compared with the operated right side. Postoperative hospital stay was the same in both groups (median 13 days; $P = 0{\cdot}86$). The hospital mortality rate was two of 101, and was not affected by the type of drainage.

Conclusion Passive drainage did not reduce hospital stay, but was as safe and effective as the active system in draining the pleural cavity after uncomplicated oesophagectomy.

Chest-tube drainage after transthoracic oesophagectomy is a necessary postoperative procedure to evacuate excessive amounts of fluid and air from the operated chest and to allow the lung to re-expand to provide adequate ventilation. Connection of the patient to a suction device in the wall reduces the patient's postoperative mobilization. In an attempt to provide postoperative mobilization, a passive pleural drainage system (Portex; Portex, Hythe, UK) was introduced, which eliminates the need to connect the patient to a wall suction device. The aim of the study was to evaluate the more easily handled passive underwater-seal drainage set by comparing it to a conventional active drainage system with respect to efficiency and security.

Patients and methods

From May 1990 to January 1996, 117 patients were admitted to the department of surgery for oesophagectomy. Before operation all patients were randomized to either an active suction drainage system ($n = 55$) or a passive drainage system (Portex; $n = 46$) for evacuation of the operated right chest. Thirteen patients were excluded because of irresectable tumours. Three patients who were randomized to the passive drainage system, but who later required active drainage because of postoperative complications, were excluded from the study. These three patients were excluded because the intention of the study was primarily to evaluate the different drainage methods in patients with an uncomplicated postoperative course. There were 72 men and 29 women operated on with an oesophagectomy and a gastric pull-up. Ninety patients were operated on because of malignant lesions and the rest for benign disorders. Malignant and benign disorders were equally distributed between the two groups ($P = 0{\cdot}17$, Fisher's exact test).

The abdomen was entered through an upper midline incision, and the stomach was isolated and transformed to a gastric tube with a linear stapling device, TLC 55 (Ethicon, Stockholm, Sweden) or GIA (Autosuture, Stockholm, Sweden). All operations were performed in a standardized way including fat and lymph node dissection in the upper abdomen and mediastinum. The thoracic oesophagus was explored through a right posterolateral thoracotomy, and the anastomoses were constructed in the apex of the right chest with a circular stapling device (Premium CEEA, cartridge size 25, 28 or 31 mm; Autosuture) or were manually sutured to the remaining oesophagus using polydioxanone (4/0 PDS II; Ethicon), through a separate cervical incision running parallel to the left sternocleidomastoid muscle. Two chest tubes (Argyle thoracic catheter, Charrière 28, Beiersdorf, Kungsbacka, Sweden) were inserted separately through the right inferolateral chest wall. One tube was placed anteriorly with the end close to the apex of the chest, and the second tube was placed in the posterior chest parallel to but 5 cm away from the oesophageal substitute, and fixed with a loop suture.

The active drainage set consisted of two connected reusable bottles which in turn were connected to a continuous suction device in the wall of the ward. The bottle connected next to the patient drained fluid. The pressure was regulated by the second bottle, which contained water and was connected to the suction device. The negative pressure was set to 15 cmH_2O, and was predetermined by adjusting the underwater level of the central metal rod through which the system communicated with the surrounding atmospheric pressure. The passive drainage bag system consisted of a smaller single-use 2000-ml lightweight plastic bottle, with an underwater seal for a one-way flow of the contents of the tubes.

Patients who were randomized to the passive drainage set were connected to this system on the first postoperative day as soon as they returned to the ward, where mobilization and physiotherapy was started. One specialized physiotherapist was responsible for the preoperative and postoperative pulmonary physiotherapy.

Postoperative bedside chest radiography was performed in the evening of the day of operation, on the third postoperative day, and as clinically necessary. When less than 200 ml of serous fluid was delivered through the drains in 24 h and there was no air leak the drains were clamped. Clamping usually began on the fifth postoperative day, after chest radiography in the erect position was done with lateral and anteroposterior projection to

---

Paper accepted 12 January 1998

evaluate the degree of pneumothorax and the amounts of fluid. Another similar chest radiograph was obtained within the next 24 h to exclude pneumothorax before removing the chest tubes. Immediately before removal of the drains, but after the radiograph was taken, the clamps were removed and controlled active suction (15 cmH_2O) was connected to the chest drains during removal. This was done to equalize the intrapleural pressure in both groups, and to prevent pulmonary injury from excessive negative intrapleural pressure during drain extraction in the passive group. No complication was noted during the clamping procedure. A follow-up chest radiograph was taken the next day, as required, and always before the patient was sent home. At least five chest radiographs were obtained, normally on days 1, 3, 5, 6 and 7 after operation.

The radiographs were reviewed and evaluated by one radiologist (C.-G.L.) who was unaware of the method of drainage used. All but five radiographs were available at the time of evaluation. The degree (mm) and duration (days) of pneumothorax were determined by examining all the radiographs taken during the hospital stay. In the authors' previous experience 20 per cent of patients who underwent this procedure had a small pneumothorax in spite of well functioning drains, and the same proportion had pleural effusions. With the new disposable passive drainage system a reduction in the frequency of pneumothorax and pleural effusions to one tenth of the previous rate was anticipated. Power calculation showed that for an 80 per cent probability of detecting such a difference, 44 patients were needed in each group.

The size of pleural effusions was estimated on anteroposterior and lateral radiographic examinations performed in the upright position because the patients were not consistently examined in decubitus position. The degree of pleural effusion was graded from 0 to 3; grade 0, no effusion; grade 1, minimal effusion (1–2 cm), grade 2, 2–8 cm; and grade 3, more than 8 cm effusion. The rate of pleural effusions and atelectases were noted separately for each lung.

Nominal data were compared with Fisher's exact test. Data from the ordinal, interval and ratio scale were analysed using the non-parametric Mann–Whitney *U* test. $P < 0{\cdot}05$ was considered statistically significant.

Results

Median hospital stay was 13 (range 9–83) days in the active drainage group and 13 (range 8–41) days in the passive drainage group ($P = 0{\cdot}86$). The three patients in the passive drainage group who were excluded from the study had a hospital stay of 13–68 days. The chest drains were removed after a median of 7 (range 5–35) days in the active groups and 7 (range 4–33) days in the passive drainage group ($P = 0{\cdot}58$).

No difference in prevalence of pneumothorax during treatment was noted between the active (nine of 55) and passive (four of 46) drainage groups ($P = 0{\cdot}20$). After the removal of the chest drains seven patients in the active drainage group had a small remaining pneumothorax (5–25 mm) and one patient in the passive drainage group had a 10-mm pneumothorax ($P = 0{\cdot}07$, Fisher's exact test any pneumothorax or not). All resolved spontaneously. No difference was noted between the two drainage groups regarding the size ($P = 0{\cdot}46$) or the duration ($P = 0{\cdot}53$) of the pneumothorax. Forty-six (active drainage) and 42 (passive drainage) patients had no pneumothorax. Pneumothorax was median 10 (range 2–20) mm in the active group and 5 (range 2–10) mm in the passive drainage group. Pneumothorax persisted for 1 (range 1–4) days in the active group and 2·5 (range 1–5) days in the passive group. The distribution of right ($P = 0{\cdot}84$) and left ($P = 0{\cdot}61$) pulmonary atelectases and the amount of right ($P = 0{\cdot}10$) and left ($P = 0{\cdot}24$) pleural effusions was equal between the two drainage systems. Forty-seven of the patients had manually sutured cervical anastomoses while 54 patients had circular stapled anastomoses in the apex of the right chest. The type of anastomosis did not affect the distribution of pneumothorax, atelectases or pleural effusions ($0{\cdot}10 < P < 0{\cdot}84$). On the contrary, there were significantly more remaining basal atelectases ($P < 0{\cdot}001$) and pleural effusions ($P < 0{\cdot}001$) in the non-operated left chest compared with the right (*Table 1*).

Anastomotic leakage or gangrene or perforations of the oesophageal substitute, which could have affected the parameters studied, were noted in seven patients (*Table 2*). Because of these complications, three of the patients with passive drainages initially were converted to active suction drainage. These three patients were excluded from the study, but are reported in the table of complications (*Table 2*). The hospital mortality rate was two of 101; both patients who died were randomized to the active drainage group. One patient died during the operation from a cardiac arrest which was resistant to medical and mechanical treatment, and subsequently never had a chest

Table 1 Pulmonary atelectases and pleural effusions at the time of discharge in patients who underwent oesophagectomy

	Right side		Left side	
Grade	Active suction drainage ($n = 55$)	Passive suction drainage ($n = 46$)	Active suction drainage ($n = 55$)	Passive suction drainage ($n = 46$)
Atelectasis

tube. The other patient died from a late necrosis of the membranous part of the trachea.

Discussion

Few publications have compared different drainage systems after chest surgery and to the authors' knowledge none after oesophagectomy and none in a highly standardized way. Alternative drainage systems such as the Heimlich valve[1] and other forms of drainage bags[2] have proved to be as good as the traditional glass bottle drainage system in chest surgery but the published series include different surgical procedures and unknown numbers and sizes of drains, making them hard to evaluate. Two drains of fixed diameter were used in the present study placed in a similar way after a standardized oesophagectomy.

The conventional active drainage system is safe but cumbersome to work with. The passive suction system is light, can easily be carried around by the patient and is easy for the staff to inspect and to handle. The passive drainage system is delivered sterilized and is a closed system which prevents migrating infections from the bottles, and has a scale for daily volume assessment. One disadvantage of the passive system is that the extent of negative intrapleural pressure varies with the amount of fluid in the chamber where the negative pressure is set. The manufacturer recommends a minimal and a maximal fluid content in this chamber, thereby assuring a proper pressure level. The fluid in the pressure-setting chamber empties automatically into a collecting chamber thereby regulating the pressure, so the maximum negative intrapleural pressure cannot reach extreme values. In the passive drainage system the actual negative intrathoracic pressure is unknown and beyond the control of the medical staff. According to the manufacturer, the negative intrapleural pressure in the passive drainage system at rest is between -2 and -5 cmH$_2$O, and during inspiration the negative intrapleural pressure decreases to about -35 cmH$_2$O[3]. If the negative pressure is reduced, for example after a coughing episode, a lower intrathoracic pressure may be set. This passive drainage method has not therefore been used routinely after anastomotic or substitute leakages. To prevent suction injuries, the posterior chest tube was anchored inside the right chest wall separately from the transposed stomach. No necrosis due to suction was noted in these patients. However, in one patient with a passive drainage set and in one in the active suction drainage group a chest tube was dislocated and the tip of the chest tube eroded the substitute with leakage as the result. Both leakages were treated successfully. It cannot be excluded that the negative pressure inside the drainage tube together with mechanical erosion from the tip of the drain resulted in the wounds described, but other factors such as defective vascular supply to the substitute may have contributed. It would be useful to be able to measure and correct improper pressure with the passive device.

The staying power of the passive drainage system seems to be as good as that of the active system because in both groups there were patients with pleural effusions of more than 200 ml per day for longer periods than a month, up to 33 days in the passive group and 35 days in the active drainage group. A clear advantage of the passive system is apparent in this respect: patients who are otherwise healthy but with a large amount of pleural drainage making removal of the drains impossible can after careful instruction leave the hospital.

The similar distribution of pneumothorax, frequency of pulmonary atelectases and pleural effusions, and median postoperative hospital stay between the groups indicated that passive drainage was as good as active drainage after oesophagectomy. Since the passive suction system did not immobilize the patient to the same extent, one might expect a shorter postoperative hospital stay in this group; however, this was not the case. To some extent this could be explained by the fact that the chest drains were removed after a median of 7 days in both groups. Thereafter the patients were immobilized for other reasons. The drainage tubes remained in place for about half of the postoperative hospital stay, and the period of recovery after removal of the tubes was unaffected by the method of drainage.

A clinically well known[4–6], and in this study well documented, difference was the dominance of basal atelectases and pleural effusions on the left side irrespective of the drainage system used. This was probably the result of the patient's position during the operation, with the left lung as the lowest point.

In conclusion, the light and convenient passive drainage bag system was as good and secure as the traditional active suction system for draining the right chest after uncomplicated oesophagectomy. There were no complications specifically attributed to the passive drainage system. Hospital stay was not affected by the type of drainage.

Background The management of chylothorax complicating oesophagectomy remains controversial. Even if medical management alone can be successful, some authors advocate early reoperation. The aim of this retrospective study was to identify the clinical variables associated with a high probability of full recovery with medical treatment.

Methods Among 850 Lewis procedures performed for oesophageal carcinoma, 23 patients (2·7 per cent) developed postoperative chylothorax despite systematic preventive ligation of the main thoracic duct. Patients who responded to conservative management were compared with those requiring reoperation for preoperative radiotherapy, unilateral *versus* bilateral pleural effusion, delay of occurrence of the chylothorax, and ratio of mean chylous output to body-weight 1 and 5 days after its onset.

Results Conservative management was successful in 14 patients with a mean(s.d.) delay of 12(5) (range 7–21) days and there were no hospital deaths. Reoperation was necessary in nine patients; there were two postoperative deaths and no recurrence of the chylothorax. The only significant difference between reoperated and medically treated patients was the mean(s.d.) chylous output at day 5: 23·5(16·6) *versus* 6·7(5·5) ml per kg body-weight ($P < 0·001$). At this time, the output was less than 10 ml/kg in 12 of 14 patients in whom medical treatment was successful (sensitivity 86 per cent), and equal to or greater than this cut-off value in all the patients who underwent reoperation (specificity 100 per cent).

Conclusion The ratio of chylous output to body-weight on the fifth day after the onset of a chylothorax complicating oesophagectomy seems to reliably predict the success of continuing medical treatment.

The close anatomical relationship between the oesophagus and the main thoracic duct explains the risk of chylothorax after oesophageal resection. Despite improvement in postoperative nutritional support, chylothorax complicating oesophagectomy remains a serious condition which may jeopardize immunological and nutritional status which is often already severely impaired in patients with cancer[1]. Primary management of chylothorax usually requires chest drainage and total parenteral nutrition[2–6]. However, the morbidity and variable efficacy of medical treatment have caused some authors to suggest early reoperation in the first week following the onset of chylothorax[7–9]. The drawback of this aggressive approach is that thoracotomy is performed a few days after the initial operation in a patient who might have recovered with conservative management. Therefore, the optimal management of postoperative chylothorax is still not clearly defined. The aim of this study was to identify early clinical variables allowing accurate indications for medical treatment or reoperation in patients with chylothorax complicating oesophagectomy.

Patients and methods

Between 1980 and 1996, 850 patients underwent a Lewis procedure for oesophageal carcinoma at this institution. During the thoracic phase, oesophageal resection included extensive lymphatic clearance with complete posterior mediastinectomy from the diaphragm to the aortic arch. The extent of supra-aortic lymph node dissection was based on the level of the tumour and the surgeon's preference. All patients underwent supradiaphragmatic ligation of the main thoracic duct posterior to the aorta along the front of the spine with a non-absorbable suture. Patients who underwent oesophagectomy without thoracotomy or cervical oesophagogastric anastomosis with cervical lymph node dissection were excluded because the extent of lymph node clearance was more variable.

Postoperative chylothorax developed in 23 patients (2·7 per cent) who were the basis of the study. There were 19 men and four women with a mean(s.d.) age of 54(11) (range 34–73) years. The diagnosis of chylothorax was suspected as early as the third postoperative day when the chest drainage output was greater than 500 ml per 24 h with a lymphocyte count of more than 50 per cent[9]. The diagnosis was confirmed by injection of a cream-rich diet through the nasogastric tube which resulted in a milky appearance of the pleural fluid. Initial management always included unilateral or bilateral chest drainage and total parenteral nutrition which was begun as soon as the diagnosis of chylothorax was established. Throughout the period of this study, the policy was to continue medical treatment for at least 12 days after which reoperation through the previous right thoracotomy was attempted if daily chylous output was greater than 500 ml or the lung was not re-expanded. Lymphography was not performed before reoperation. A cream-rich diet was given before operation to facilitate localization of the chylous leak.

The influence of five variables on the outcome of postoperative chylothorax was analysed including: preoperative radiotherapy, bilateral pleural effusion, delay of onset of chylothorax after oesophagectomy, and ratio of chylous flow to body-weight on day 1 and day 5 following the onset of chylothorax[1,10].

Data are expressed as mean(s.d.). The Mann–Whitney *U* test was used to compare non-parametric data. Other data were compared by the χ^2 test. $P < 0·05$ was considered to be statistically significant.

Paper accepted 4 March 1998

Results

Conservative treatment resulted in recovery in 14 patients. In these patients, chest drainage was stopped after 9(5) (range 3–17) days and food intake was begun within 12(5) (range 7–21) days without recurrence of the chylous effusion. Conservative treatment was complicated in one patient who developed sepsis from the central venous access.

In nine patients, conservative treatment did not successfully stop the chylous leak. These patients were reoperated after 18(6) (range 12–27) days. In eight patients, the leak was located on the right side of the descending aorta or at the aortic arch. These patients underwent a more caudal repeat ligation of the thoracic duct. Ligation included all surrounding tissue, and was associated with direct suture of a visible leak in five patients. In another patient, the chylous leak originated on the left side of the descending aorta from lymphatic ducts which were ligated. Pleural decortication was performed in five reoperated patients. Seven patients had an uneventful postoperative course. Two reoperated patients died from sepsis related to an anastomotic leak, without recurrence of the chylothorax. One of these leaks was discovered at the time of repeat thoracotomy while the other developed after reoperation.

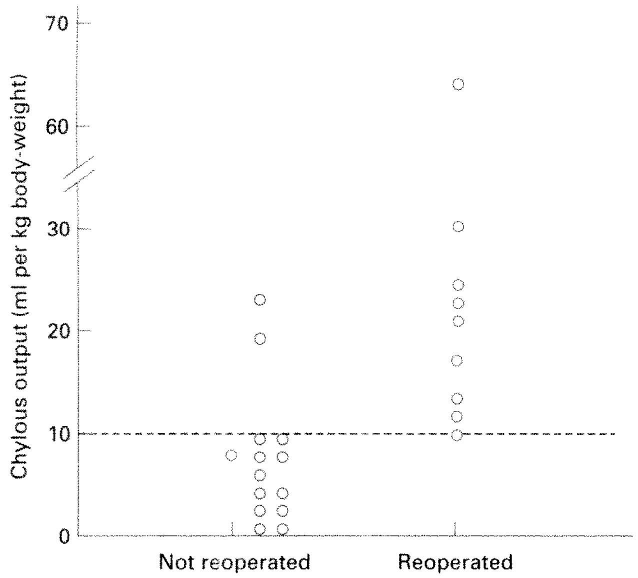

Fig. 1 Distribution of the daily chylous output to body-weight ratio on day 5 after the onset of chylothorax in non-reoperated and reoperated patients

Characteristics of patients in whom conservative treatment was successful and of those who required reoperation are summarized in *Table 1*. On the fifth day following the onset of chylothorax, the mean chylous output to body-weight ratio was significantly lower in patients who were treated conservatively than in those in whom a subsequent reoperation was performed. Chylous outflow on the fifth day of medical treatment was below 10 ml/kg in 12 of the 14 patients who did not require reoperation (sensitivity 86 per cent) and equal to or greater than this cut-off value in all the patients who did undergo reoperation (specificity 100 per cent) (*Fig. 1*).

Discussion

In the present study, a daily chylous loss of 10 ml/kg at day 5 after the onset of the chylothorax was reliable for differentiating patients in whom medical treatment succeeded from those who had a reoperation. Reoperation was avoided in all patients with a chylous output less than this cut-off value. In contrast, in patients with a chylous output exceeding this cut-off value, indication for reoperation should be balanced by the mortality rate observed in the present series (two of nine patients). Patients were selected for reoperation on the volume of output, and it is possible that some chylous leaks may have closed spontaneously in this group.

For most authors, management of chylothorax requires chest drainage and total parenteral nutrition[2–6]. Conservative management alone allows closure of the fistula in up to 80 per cent of patients within 2–5 weeks but can lead to some metabolic and septic complications when sustained[4,5]. In the series of Marts *et al.*[5], the mean duration of medical treatment alone was 13 days and the mortality rate was 8 per cent. In contrast, Bolger *et al.*[4] reported a 50 per cent mortality rate when the treatment lasted for a mean of 35 days. In the present series, no patient died with conservative treatment; this result probably reflects the short duration of the treatment, which lasted a mean of 12 days in patients who were treated conservatively and 18 days in reoperated patients.

To minimize the adverse effects of chylothorax, some authors have suggested rapid reoperation to close the chylous leak no later than 1 week after its occurrence[7,8,11]. Early reoperation allows easy localization of the leak before postoperative adhesions have developed. The success rate of reoperation was as high as 90 per cent with no hospital deaths in a series of 11 cases of chylothorax complicating 320 transhiatal oesophagectomies[7]. This result does not seem to be directly applicable to the present patients. In Orringer's series[7], the lack of previous thoracotomy probably facilitated access to the mediastinum and allowed ligation of the duct without exposing the cervical anastomosis. In patients with a thoracic anastomosis, reoperation can be harmful as suggested in one patient in the present study who developed fatal anastomotic leakage 2 days after reoperation.

Some groups have defined criteria for reoperation after failure of medical treatment. Preoperative radiotherapy, which has been suggested to increase the prevalence of postoperative chylothorax[12], did not influence the need for reoperation in the authors' experience. A bilateral pleural effusion[6] was not more frequent in reoperated patients of the present series than in those who did not undergo reoperation. For Patterson *et al.*[13], operation is indicated if a daily chylous loss of 1 litre or more persists for more than 1 week. Teba *et al.*[3] recommend reoperation for a chylous loss exceeding 1·5 litres per day for 5 days or persisting for more than 2 weeks. The onset of nutritional complications is also an indication for surgery[2]. The authors' policy was to continue medical treatment for a minimum of 12 days before undertaking a repeat thoracotomy, since this delay was considered to be optimal for anastomotic healing, the onset of adhesions and an effective duration for medical treatment. The results of the present study suggest that reoperation may be decided after the fifth day of medical treatment. However, the optimum delay before performing reoperation with a low rate of complications cannot be determined from this study.

In the present series of 850 patients from a single centre there was a 2·7 per cent rate of chylothorax complicating a Lewis procedure despite systematic preventive ligation of the main thoracic duct. This result is comparable to that of Dougenis *et al.*[8] who reported a 2·1 per cent rate of chylothorax after oesophagectomy including preventive ligation of the main thoracic duct. Anatomical variations encountered in up to 40 per cent of patients[14,15] probably explain the chylous leak located on the left side of the descending aorta which was observed in one reoperated patient. In the eight other reoperated patients, the cause of the chylous leak was a technical failure. In these cases, the ligation was either too cranial in the mediastinum or too restricted and did not include all the collaterals of the main thoracic duct. In these eight patients, a repeat ligation which included all tissues located between the right side of the aorta, the spine and the mediastinal pleura was performed successfully[16].

In conclusion, medical management was successful in 14 of 23 patients who developed chylothorax after a Lewis procedure including preventive ligation of the main thoracic duct. A daily chylous output of less than 10 ml/kg after 5 days of medical treatment is reliable for predicting successful medical treatment which in this study occurred within a mean of 12 days. Otherwise, reoperation by repeat thoracotomy should be planned taking into account its associated mortality rate.

Background It is unclear why some patients with a columnar-lined oesophagus present with intestinal metaplasia and others do not. The physiopathological and clinical implications of the length of the metaplastic segment are also controversial. The aim of the study was to determine whether the length of the metaplasia and the presence of intestinal epithelium are related to the clinical, manometric and pHmetric data in patients with columnar-lined oesophagus.

Methods A comparison of clinical, endoscopic, pathological, manometric and pHmetric data was made between patients with columnar-lined oesophagus of 3–5 cm ($n = 31$) and those with a metaplastic segment of 5 cm or more ($n = 28$); the same comparison was made between patients who had specialized intestinal metaplasia ($n = 37$) and those who did not ($n = 22$).

Results No significant difference was found in any of the variables studied except for associated inflammatory lesions above the columnar epithelium which were more frequent in patients with a shorter metaplastic segment ($P < 0{\cdot}05$).

Conclusion Neither the length of the metaplastic segment nor the presence of intestinal metaplasia was related to a more evolved gastro-oesophageal reflux disease, a poorer oesophageal clearing function or higher acid reflux rates.

It is unknown why some patients with a columnar-lined oesophagus develop intestinal metaplasia and others do not. It is also unclear why the length of the metaplastic segment varies greatly between patients, there being little information in the literature on the determining factors. The duration of symptoms, presence of bile and pancreatic juice in the refluxed material, toxic habits (smoking, alcohol etc.) and individual factors (age, sex, heredity) may be involved.

The aim of this study was to investigate in a group of 59 patients with circumferential columnar-lined oesophagus whether the length of the metaplastic segment and the presence of specialized epithelium are related to the patients' epidemiological, clinical, endoscopic, histological, manometric and pHmetric data.

Patients and methods

The current concept of Barrett's oesophagus includes not only cases of circumferential metaplasia, over 3 cm in length and continuing into the cardia[1], but also those which, arranged in tongues or islets or measuring less than 3 cm in length, present with intestinal or specialized metaplasia[2]. This redefinition underlines the importance of intestinal metaplasia as a premalignant lesion. However, as this study was carried out in 59 patients diagnosed with columnar-lined oesophagus between January 1982 and January 1993 in this department, it does not include those patients currently defined as having 'short Barrett's'[3]. In all the patients endoscopy showed a circumferential metaplasia of over 3 cm in length in the distal oesophagus and continuous with the cardia, which was confirmed histologically.

To assess the importance of the length of the metaplastic segment the patients were divided arbitrarily into two groups: group 1 ($n = 31$) when the length of the metaplasia was between 3 and 5 cm, and group 2 ($n = 28$), when it was 5 cm or more. In the same way, to assess the importance of the intestinal metaplasia, the patients were divided into another two groups according to whether they presented with intestinal columnar-lined oesophagus (ICLO) ($n = 37$) or gastric columnar-lined oesophagus (GCLO) ($n = 22$) epithelium in the biopsies of the metaplastic segment. All patients underwent clinical, endoscopic, histological, manometric and pHmetric assessment.

Clinical assessment was done by personal interview using a questionnaire. Smokers or ex-smokers of more than five cigarettes per day fell into the 'smoking' group. Alcohol intake exceeding 280 g per week or 40 g per day in men, and 168 g per week or 24 g per day in women was considered as 'alcohol abuse'.

Endoscopy was performed in all patients by the same endoscopist using a flexible fibre endoscope (Olympus q-10, Tokyo, Japan). The following reference points were taken: incisors, squamocolumnar junction (Z line) and cardia. The cardia was identified by the highest gastric fold and by the interruption of deglutition waves. The hiatus was also identified in all cases, a hiatus hernia being present in all but one patient. The length of the metaplastic segment was calculated by subtracting the distance from the incisors to the proximal edge of the metaplastic segment and that of the cardia. Biopsies were taken systematically as follows: the first four samples (one in each quadrant) immediately proximal to the squamocolumnar junction, the next four immediately distal to the same, and the rest at 2-cm intervals in a caudal direction in each quadrant. Also considered for the study were endoscopic data on the presence of Barrett's ulcers, stenosis and oesophagitis. The median number of biopsies was 12 (range 12–20) in group 1 and 16 (range 16–24) in group 2. All biopsies were studied by the same two expert pathologists with an interest in Barrett's oesophagus.

The biopsies were analysed histologically by haematoxylin–eosin staining. The metaplasia was classified into four variants[4]: fundic, junctional, intestinal and mixed (when there was a combination of the others).

Twenty-four-hour pH monitoring and oesophageal manometry were performed in all patients. The characteristics of the equip-

Paper accepted 21 January 1998

ment and method used in both tests have been described previously[5].

Data are presented as mean(s.d.). Comparisons of means were made by the Wilcoxon non-parametric test. Comparison of the frequencies of qualitative variables in independent samples was made by χ^2 test with Fisher's exact test where necessary. Differences were considered statistically significant when $P<0·05$.

Results

As far as the length of the columnar-lined oesophagus is concerned, no differences were found in the ratio of sexes, age, percentage of smoking or alcohol abuse, initial symptoms or duration of symptoms (*Table 1*). Patients with a shorter columnar-lined oesophagus had a greater percentage of associated inflammatory lesions above the metaplastic segment ($P<0·05$). No other significant differences were found regarding other peptic complications associated with the columnar-lined oesophagus, such as ulcers and/or stenosis (*Table 2*). Patients with a longer metaplastic segment did not show a greater prevalence of intestinal metaplasia.

The manometric study revealed a defective lower oesophageal sphincter (LOS) in both groups, but with no significant differences. There was no difference in the motor function of the distal oesophagus. Twenty-four-hour pH monitoring showed pathological rates of acid gastro-oesophageal reflux in both patient groups, with no statistically significant differences between them (*Table 3*).

Discussion

Although it is generally accepted that columnar-lined oesophagus is a condition acquired as a result of severe prolonged gastro-oesophageal reflux, Little[6] has suggested that the origin of the metaplasia could depend on its length. According to this author, metaplastic segments of less than 5 cm in length would probably be related to pathological gastro-oesophageal reflux, whereas longer metaplastic segments would represent congenital or developmental alterations. The present data suggest that the length of the metaplasia is not related to symptoms or their duration, which is in agreement with Cameron *et al.*[7–9], who claim that the columnar-lined oesophagus quickly attains a certain length and then becomes stable.

From a functional point of view, Mason and Bremner[10] relate the spread of metaplasia to impaired motor function of the oesophageal body (smaller amplitude and

longer duration of peristaltic waves), suggesting 'a progressive deterioration of oesophageal motility with advanced disease'. These authors thus establish a parallel between the length of the metaplasia, stage of the disease and degree of deterioration of motor function. The present results, however, do not support this statement since the group of patients with a longer metaplastic segment did not have a more defective LOS, a poorer clearing function of the oesophageal body or higher rates of gastro-oesophageal reflux. The discrepancy with Mason and Bremner's data may be related to the fact that they did not study LOS pressure or quantify gastro-oesophageal reflux, and could have been comparing two groups of patients with different reflux rates.

Special consideration should be given to patients currently regarded as having 'short Barrett's'[3], i.e. lesion less than 3 cm in length but with histological evidence of intestinal metaplasia, in many cases without endoscopic signs or symptoms of reflux disease. Little is known about the relation of short Barrett's to gastro-oesophageal reflux and its possible neoplastic degeneration. This study does not include such patients, since the classical definition of 'Barrett's oesophagus' was used. However, for Spechler and Goyal[3], the presence of specialized-type epithelium, the neoplastic potential of which is widely documented, is a condition that is not only sufficient, independent of its length, but necessary for diagnosing Barrett's oesophagus. Therefore, their concept of 'Barrett's oesophagus' would exclude patients with long segments of columnar-lined oesophagus in which only the presence of gastric-type epithelium is detected. In the present study, the patients with specialized-type epithelium did not have longer-lasting symptoms or greater deterioration of oesophageal function. Moreover, the rate of acid gastro-oesophageal reflux was similar in patients with gastric-type and intestinal-type epithelium. Thus it is unclear why some patients develop a columnar-lined oesophagus with intestinal-type metaplasia and others with the same physiopathological condition (advanced gastro-oesophageal reflux disease), develop the gastric type. Other factors may be involved such as biliopancreatic reflux to the oesophagus[11,12], the severity of the initial lesion in the epithelium or the intimate differentiation mechanisms of the pluripotential cells that cause the metaplasia[13–15]. It has been suggested that the longer the metaplastic segment the more frequent the presence of intestinal metaplasia[3], although in this study no significant relation was found between these two variables, and the possibility of there being areas of intestinal metaplasia within the segment of columnar metaplasia that have gone unnoticed seems remote, considering the number of biopsies performed. Furthermore, a number of reports[16,17] describe patients with columnar-lined oesophagus extending well up the oesophagus in whom biopsy specimens showed only junctional or gastric fundic-type epithelia.

In conclusion, these results show that patients with long segments of columnar-lined oesophagus or with specialized intestinal epithelium do not have more advanced gastro-oesophageal reflux disease, poorer oesophageal clearing or higher reflux rates. Therefore, from the point of view of gastro-oesophageal reflux disease they do not require a different therapeutic approach. However, since the degenerative potential of specialized intestinal epithelium is widely documented, endoscopic surveillance is required in these patients, whereas it still has to be determined in patients with gastric-type epithelium.

Background Viscous macromolecules and phospholipids have been shown to reduce postoperative adhesion formation. The ideal agent, or combination of agents, still remains to be identified.

Methods The effect of hydrophobically modified ethyl (hydroxyethyl) cellulose (HM-EHEC) and polyquarternium-24 (LM-200), two cellulose-derived polymers, and of sphingomyelin, was examined in an animal model. Adhesions were induced in the parietal peritoneum in a standardized manner and quantity, and the morphology of adhesion formation was evaluated after 7 days.

Results A significant reduction in adhesion formation was seen in animals receiving LM-200 ($P = 0{\cdot}013$) and HM-EHEC ($P = 0{\cdot}012$) as a short-term treatment compared with controls given saline, but not in animals receiving sphingomyelin ($P = 0{\cdot}733$). Additional effects were seen in the animals receiving LM-200 as a prolonged treatment ($P < 0{\cdot}001$) compared with controls. There was no difference in the magnitude of the inflammatory response between the groups.

Conclusion These results suggest that hydrophobically modified polymers are efficient in reducing adhesions, without affecting the inflammatory response.

Adhesion formation is a well known complication of abdominal and pelvic surgery, that not only renders reoperation more difficult but is also the most common cause of small bowel obstruction and mechanical infertility[1–3]. A recent survey showed that the annual medical expenditure for adhesive small bowel obstruction was almost £12 million[3]. Various methods and agents have been investigated to prevent adhesion formation, but as yet few have been proven to be effective.

The mesothelial cells of the peritoneum are covered with a film 5 μm thick. This thin layer contains significant concentrations of phospholipids, mainly phosphatidylcholine, phosphatidylethanolamine and sphingomyelin exerting surface activity[4]. The surfactants are easily destroyed by trauma, ischaemia and infection, which elicit phospholipases. In addition the light from surgical theatre lamps is known to induce lipid peroxidation, thereby interfering with phospholipid structure and function[5]. Exogenous phospholipids have been shown to reduce postoperative adhesions[6,7], possibly by providing a lubricant layer replacing endogenous hydrolysed phospholipid.

The ideal lipid, or combination of lipids and polymers, still remains to be identified. Cellulose consists of linear polymers of glucose residues. Binding of water leads to the formation of a gel. The hydrophobic modification of the surfactant polyquarternium-24 (LM-200) and hydrophobically modified ethyl (hydroxyethyl) cellulose (HM-EHEC), two cellulose-derived polymers, adds an affinity for the lipid–water interface likely to be at the injured site/cellular surfaces. Sphingomyelin has a structure similar to that of phosphoglycerides such as phosphatidylcholine but should, at least theoretically, be less susceptible to hydrolysis by lipases and phospholipases[8].

The precise mechanism of action of phospholipids and polymers is yet to be determined. In addition to their proposed mechanical function in separating and lubricating surfaces they are likely to have biological functions. Phospholipids are the substrate for arachidonic acid and sphingomyelin (95 per cent by weight), a major constituent of cell membranes. Cellulose-derived polymers are not endogenous and may therefore increase the inflammatory response.

The objectives of the present study were twofold; to test the primary hypothesis that sphingomyelin, HM-EHEC and LM-200 may reduce the formation of adhesions, and to investigate whether they affect the local inflammatory response or not.

Patients and methods

Animals

Some 154 female NMRI (US Naval Medical Research Institute) mice weighing 30–35 g were used. The experiments were approved by the local ethics committee. The animals had free access to pellets and water before and after surgery. They were allocated randomly to different experimental groups.

Compounds

Sphingomyelin (95 per cent by weight) was obtained from Swedish Dairy's Association, Research Department, Lund, Sweden. The sphingomyelin was diluted in sterile water to a final concentration of 1 per cent by weight. HM-EHEC (1 per cent by weight), a cationic polymer with five hydrophobic tails, was obtained from Akzo Nobel Surface Chemistry, Stenungsund, Sweden. LM-200 (1 per cent by weight) was obtained from Bionord, Gothenburg, Sweden. The compounds were kept refrigerated until used.

HM-EHEC is a soluble polymer that has been chemically modified to be hydrophobic, yet soluble in water. LM-200 is a polymeric ammonium salt of hydroxyethylcellulose, with a hydrophilic backbone and lipophilic pendant groups, which adds an affinity for the lipid–water interface. Solutions of hydrophobically modified polymers have been found to have higher viscosities than solutions of their unmodified analogues[9], a feature that may be of importance for mechanical separation of adjoining traumatized surfaces.

Paper accepted 23 January 1998

Experimental design

One group ($n = 6$) underwent sham operation. Three groups were subjected to a short-term treatment and three groups were given a prolonged treatment.

The short-term treatment consisted of an intraperitoneal injection of either LM-200 ($n = 21$), HM-EHEC ($n = 21$) or sphingomyelin ($n = 16$) after closure of the abdominal cavity. Controls received saline ($n = 16$). The volume load was 0·75 ml (0·25 mg per g body-weight). The groups receiving prolonged treatment were given an intraperitoneal injection of either LM-200 ($n = 21$), HM-EHEC ($n = 21$) or sphingomyelin ($n = 16$), not only at the time of the operation but also on days 2 and 3 after operation. Controls received saline ($n = 16$). The volume load was the same on all three occasions (0·75 ml). Two animals from each group were killed on days 1, 3, 5 and 7 for morphological analysis of the tissue response.

Surgical technique

Anaesthesia was induced and maintained by inhalation of methoxyflurane. The abdomen was shaved and opened with a 2·5-cm midline incision. A 2 × 15 mm defect in the parietal peritoneum was created on each side of the lateral side wall by sharp incision along a metal ruler followed by excision with a pair of scissors. The lesion was closed with four 5/0 silk sutures, one at each end of the lesion and the other two at equal distance in between. The midline incision was closed in two layers by continuous 3/0 polyglycocolic mass closure (Dexon, Davis and Geck, St Louis, Missouri, USA). The procedure is described in detail elsewhere[10,11].

Evaluation

The objective was both to quantitate the formation of adhesions and to study the morphological response in the tissue. At days 1, 3 and 5 after operation, two animals from each group were killed by an overdose of isoflurane and biopsies were taken for morphological studies. Seven days after the operation the remaining animals were killed. The abdominal cavity was opened widely with a U-shaped incision with its base to the right of the animal. The flap was then turned over to the right so that the parietal peritoneum of the anterior abdominal wall and the adhesions attached to it were displayed. The lesions previously induced in the peritoneum were identified by the suture lines. The lengths of the original lesion and of the individual adhesion attachments were measured with a calliper. The percentage of the peritoneal defect that was covered with adhesions could then be calculated according to the formula: adhesions (%) = sum of attachments (mm)/excision site (mm) × 100 as described previously[10,11]. Besides quantification, the location and number of attachments were noted.

Morphology

The injured area was excised, including the parietal peritoneum, muscular layer and skin. The specimen was fixed in Bouin's solution for 24 h, dehydrated and embedded in paraffin wax. Sections were cut at a thickness of 5 μm and stained with haematoxylin and eosin.

Statistical analysis

Values are given as mean(s.e.m.). The non-parametric Mann–Whitney U test was used to determine the significance of differences in adhesion formation between groups. A P value less than 0·05 was considered statistically significant.

Results

None of the animals had adhesions at the beginning of the operation. All animals developed adhesions, except for two animals receiving LM-200 as a prolonged treatment. No animal developed bowel obstruction or displayed signs of general malaise.

Adhesion formation

The sham-operated group had no adhesions after operation, except at the midline incision. There was no significant difference in adhesion formation between the control group (69·0(4·5) per cent) and the group that was given sphingomyelin (69·7(6·7) per cent) ($P = 0·733$) as a short-term treatment (*Fig. 1*). The HM-EHEC-treated group had significantly less adhesion formation (48·1(5·1) per cent, $P = 0·012$) than the control, as did the group given LM-200 (44·2(6·3) per cent, $P = 0·013$). Repeating the injection of sphingomyelin 2 and 3 days after operation gave a reduction in adhesion formation (72·4(4·5) per cent, $P = 0·049$) compared with saline controls. Significantly fewer adhesions were seen in the groups receiving the long-term treatment with HM-EHEC (47·6(6·5) per cent, $P = 0·003$) or LM-200 (24·4(5·3) per cent, $P < 0·001$) compared with the control group given three injections of saline (84·5(6·2) per cent). There was no difference in effect between the group receiving HM-EHEC as a short-term treatment (48·1(5·1) per cent) and that receiving HM-EHEC as a prolonged treatment (47·6(6·5) per cent) ($P = 0·747$). The adhesion-reducing effect of LM-200 was significant with both the short- and long-term treatment but, in contrast to HM-EHEC, LM-200 was significantly more effective when given as a prolonged treatment (24·4(5·3) per cent) compared with the short-term treatment (44·2(6·3) per cent) ($P = 0·032$).

The number of adhesion attachments to different intra-abdominal structures (omentum/pelvic fat bodies (PFB); bowel; or other structures (predominantly liver)) was also

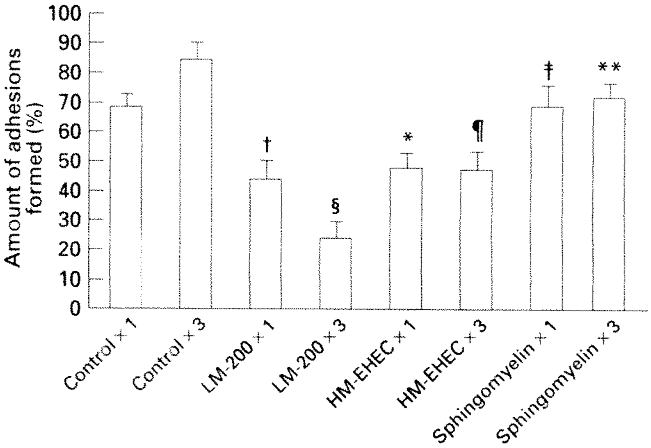

Fig. 1 Adhesion formation in animals subjected to different treatments. Values are mean(s.e.m.). Controls received saline as a single dose (control × 1) or for 3 consecutive days (control × 3). Treatment groups comprised animals receiving polyquarternium-24 (LM-200), hydrophobically modified ethyl (hydroxyethyl) cellulose (HM-EHEC) or sphingomyelin once (LM-200 × 1, HM-EHEC × 1 and sphingomyelin × 1) or three times (LM-200 × 3, HM-EHEC × 3 and sphingomyelin × 3). LM-200 and HM-EHEC were equally effective when administered once, but the performance of LM-200 was further improved by repeated administration. Sphingomyelin was less effective. *$P = 0·012$, †$P = 0·013$, ‡$P = 0·733$ *versus* control × 1, §$P < 0·001$, ¶$P = 0·003$, **$P = 0·049$ *versus* control × 3 (Mann–Whitney U test)

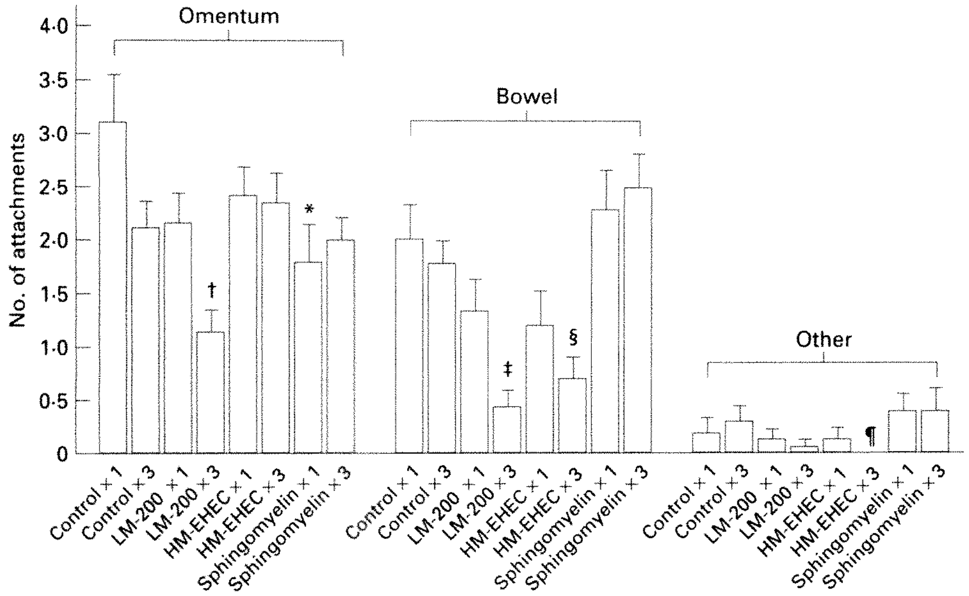

Fig. 2 Number of adhesion attachments to abdominal organs in animals subjected to different treatments. Values are mean(s.e.m.). A single administration (× 1) of polyquarternium-24 (LM-200), hydrophobically modified ethyl (hydroxyethyl) cellulose (HM-EHEC) or sphingomyelin did not significantly affect the number of attachments, whereas repeated administration (× 3) did in animals receiving LM-200 or HM-EHEC. $^*P = 0{\cdot}049$, $†P = 0{\cdot}023$, $‡P < 0{\cdot}001$, $§P = 0{\cdot}004$, $¶P = 0{\cdot}032$

studied (*Fig. 2*). LM-200 had no significant effect on the number of adhesions, given as a short-term treatment (PFB, $P = 0{\cdot}098$; bowel, $P = 0{\cdot}114$; other structures, $P = 0{\cdot}717$) compared with controls, nor did HM-EHEC (PFB, $P = 0{\cdot}205$; bowel, $P = 0{\cdot}103$; other, $P = 0{\cdot}717$). Sphingomyelin reduced the number of attachments to omental structures, but not to bowel and other parts of the abdominal cavity (PFB, $P = 0{\cdot}049$; bowel, $P = 0{\cdot}434$; other, $P = 0{\cdot}342$).

LM-200 given in three consecutive doses gave a significantly reduced number of attachments to both omentum ($P = 0{\cdot}023$) and bowel ($P < 0{\cdot}001$) but not to other structures ($P = 0{\cdot}147$). HM-EHEC reduced the number of attachments to bowel ($P = 0{\cdot}004$) and other structures ($P = 0{\cdot}032$) but not to omentum/PFB ($P = 0{\cdot}596$). Given as a long-term treatment, sphingomyelin had no effect on the number of attachments to any of the structures involved (PFB, $P = 0{\cdot}720$; bowel, $P = 0{\cdot}091$; other, $P = 0{\cdot}888$). Prolonged LM-200 treatment gave significantly fewer adhesions to both omentum/PFB ($P = 0{\cdot}023$) and to bowel ($P = 0{\cdot}032$) compared with the group that received the short-term treatment, but not to other structures ($P = 0{\cdot}549$).

Tissue response

An inflammatory reaction was seen at the site of adhesion formation, not only at the attachment site and in the abdominal wall, but also in the adherent non-injured tissue. On day 1 after surgery polymorphonuclear neutrophils dominated and later macrophages were abundant. A uniform morphological appearance was seen on specimens obtained from all groups, and there was no difference between the treatment groups and the control group. Furthermore, there was no difference between the groups given short-term and long-term treatment.

Discussion

In this study hydrophobically modified polymers such as LM-200 and HM-EHEC significantly reduced the amount of postoperative adhesion formation in an experimental model and prolonging the treatment of LM-200 reduced the number of attachments as well as the amount of adhesions. Sphingomyelin, which is structurally related to phosphatidylcholine, had beneficial effects on the amount of adhesions only when given repeatedly, but reduced the number of attachments to omentum in the short-term group.

The experimental model was chosen because it is a strictly standardized quantitative model mimicking abdominal surgery and has previously been shown to be reproducible with a low variability in the amount of adhesions formed[10,11]. Furthermore, the model enables the study of adhesion formation from two different perspectives: the amount of adhesions covering a standardized lesion and the number of attachments to the lesion and organs involved. It seems reasonable to assume that the amount of adhesions covering a standardized lesion accurately reflects the adhesiogenic stimuli to that site and that the organs involved are of importance, but the significance of the number of attachments remains to be validated. Nevertheless, there was fairly good agreement between the amount of adhesions formed and the number of attachments indicating that they represent the same thing. Mice were used, not only because they are cheap and practical to work with but also because in this model they have a relatively high frequency of involvement of non-injured bowel compared with other species[11]. From a clinical point of view this was considered an advantage, since complications often arise from adhesions involving the bowel.

The kinetics of degradation and absorption of sphingomyelin, LM-200 and HM-EHEC in the abdominal cavity are unknown so both short- and long-term treatments were studied. Furthermore, since the mechanism of action was unclear, the duration of administration required was uncertain. Physical barriers have been demonstrated to effectively reduce the formation of adhesions if they separate surfaces for at least 36 h[12], and therefore a 3-day treatment was believed to be sufficient.

Previously, soluble phosphatidylcholine has been shown to reduce postoperative adhesions[13], whereas insoluble phosphatidylcholine liposomes had the opposite effect[14]. Sphingomyelin forms liposomes in analogy to related saturated phosphatidylcholine systems[8]. In the case of phosphatidylcholine liposomes, impaired macrophage function and reduced lymphatic absorption due to enhanced net ultrafiltration was considered to be involved in the adhesion promoting effect. This might partly explain why sphingomyelin was less efficient than the other agents in reducing adhesion formation.

Plasminogen activator plays a crucial role in fibrinolysis, which is suppressed by surgical manipulation[15,16] and is pivotal in adhesion formation[17]. Mayer and co-workers[18] investigated the effect of dextran and other viscous polymers on peritoneal plasminogen activator activity and showed that the polymers investigated reversibly suppressed tissue-bound plasminogen activator and impaired the secretion of peritoneal plasminogen activator activity. This suggests a possible mechanism of action for polymer coating in reducing adhesion formation by impairing the shedding of the enzyme, thereby producing a high local concentration of plasminogen activator activity on peritoneal surfaces.

A steric–osmoic antiadhesive effect is probably one important mechanism of action of these substances. In forming a film covering the injured peritoneum they keep intra-abdominal structures from coming into continuous, close apposition by fibrin, thereby preventing adhesions from forming. This may be accomplished if the polymers inhibited the attachment of fibrin. Another possibility is that these polymers modify the polymerization or cross-linking of fibrin monomers, thereby reducing the 'stickiness' of deposited fibrin.

The reason for the increased efficacy of LM-200 but not of HM-EHEC, when given in three consecutive doses, may be attributable to electrostatic interactions. LM-200, being positively charged, will have a tendency to associate with negatively charged surfaces. However, it may also indicate that their biological effects and mechanism of action are different. None of the compounds investigated affected the inflammatory response as judged from the amount of cells present, but the functional characteristics of the cells were not investigated and may have been different between LM-200 and HM-EHEC groups.

The cellulose-derived polymers investigated were efficacious in reducing the formation of adhesions without affecting the inflammatory response and one of them was more effective if given repeatedly. The mechanism of action remains unclear, but there may be multiple actions including the separation of surfaces, increasing the local tissue plasminogen activator levels and altering the adhesive properties of fibrin. Two cellulose-derived membranes are currently approved for clinical use (Interceed, Johnson and Johnson, New Brunswick, New Jersey, USA; Seprafilm, Genzyme, Cambridge, Massachusetts, USA). However, the safety of polymers used in the present study requires further investigation before being applied in clinical practice.

Pathological appearance of the stomach after endoscopic mucosal resection for early gastric cancer

Sir

We read with interest the findings presented by Korenaga *et al.* (*Br J Surg* 1997; **84**: 1563–6) regarding endoscopic mucosal resection (EMR) of gastric cancer. There is no doubt that EMR plays an important rôle in the management of this disease, especially in Japan where extensive experience has been gained. This study, however, appeared to disregard essential criteria for the selection of patients for EMR established by Sano *et al.*[1] over 5 years ago which allowed selection of a subgroup of patients with early gastric cancer with minimal risk of lymph node metastasis where endoscopic treatment would not compromise the curative intent.

Disease confined to the mucosa is the most important of the established criteria and yet six of 11 tumours had submucosal spread. Lesions greater than 15 mm in diameter are not suitable for EMR but were included in this study resulting in incomplete excision. Finally type IIc tumours with ulceration were included in this study and lymph node metastases were found in some of these patients.

The authors do not make clear the reasons for subsequent surgery. For example, why did some patients with recurrent disease proceed to further EMR while others with positive resection margins proceeded to surgery? What was the protocol regarding management of these patients?

This paper has highlighted some of the pitfalls in the use of EMR for gastric cancer and confirmed the importance of limiting its use to those who fulfil carefully established criteria and in whom EMR will not compromise potential cure. The finding of lymph node metastases in patients treated endoscopically is unacceptable.

Author's reply

Sir

We thank Kundu *et al.* for their constructive comments. Of course, cure is a mandatory goal for the treatment of early gastric cancer. In earlier years, EMR remained a challenge. From this retrospective analysis we found that accurate diagnosis of width and depth of invasion must be assessed before EMR. Improvements in recent years may be a result of the use of endoscopic ultrasonography before EMR to assess the depth of invasion and the application of electrocautery to destroy cancer cells around the resected margin.

Assessment of the depth of invasion from an endoscopically resected specimen is important in making therapeutic decisions. The present policy is to perform subsequent surgery when (1) there is infiltration of cancer cells in the submucosal layer, or (2) lymphatic or vascular invasion is observed. If malignant cells are likely to remain in the mucosa around the resected margin but the submucosal layer is not invaded, repeated EMR is the treatment of choice. Our paper confirmed that understanding the indications and limitations of EMR is necessary. We agree that EMR should be indicated for carefully selected patients with early gastric cancer with minimal risk of lymph node metastases.

Hereditary breast cancer

Reply to letter published in previous issue (*Br J Surg* 1998; 85: 570–1)

Sir

We would like to thank Hicken *et al.* for the interest they have shown in our Review (*Br J Surg* 1997; **84**: 1334–9). We acknowledge that we did not provide strict guidelines on the management of these patients because our understanding in this area is rapidly evolving and remains controversial.

As an example, Hicken *et al.* correctly quote our review saying that the lifetime risk for carriers of *BRCA1* mutations is 50–60 per cent. Since publication of the Review, this fact is now disputed by a recent large study suggesting that the lifetime risk for *BRCA1* carriers of developing ovarian cancer is closer to 16 per cent[1].

Hicken *et al.* make a reasonable suggestion for performing laparoscopic oophorectomy as adjuvant therapy for patients with *BRCA1*-associated cancer and suggest that this should be performed for those with *BRCA2*-associated breast cancer. The latter would not reduce any potential risk of developing ovarian cancer as *BRCA2*-mutations are not associated with an increased risk of developing ovarian cancer.

Effect of a no-conversion policy on patient outcome following laparoscopic cholecystectomy

Sir

We share the concerns expressed by Wallace and O'Dwyer (*Br J Surg* 1997; **84**: 1680–2) on the potential lack of experience of open cholecystectomy by surgical trainees in the laparoscopic era. We feel that their paper did not adequately address this issue.

The not insignificant number of open cholecystectomies performed during the no-conversion period and the admirably short time taken for trainees to perform the laparoscopic procedure attest to a successful case selection policy in this unit. The reasons for conversion to an open procedure before adoption of the no-conversion policy included haemorrhage and failure to define anatomy. Are the authors suggesting that the surgeon should always persist with the laparoscopic procedure in the face of such difficulties? We find it particularly difficult to justify their conclusion that the inexperienced surgeon should consider laparoscopic subtotal cholecystectomy or cholecystostomy with stone removal in preference to open cholecystectomy when the one such patient in their series required an open operation at 48 h for major complications with this approach.

Conversion to an open procedure in difficult cases is justified and attention should thus focus on the adequate training of surgical trainees in surgical procedures that will enable them to cope adequately.

Author's reply

Sir

I am sure that Garden *et al.* would agree that the reasons for conversion (haemorrhage and failure to define anatomy) occur less frequently as experience is gained with laparoscopic cholecystectomy. I am also sure that even they may need to revert to cholecystostomy or subtotal cholecystectomy for the occasional gallbladder that resists both laparoscopic and open cholecystectomy.

Correlation between blood loss and inferior vena caval pressure during liver resection

Sir

We read with interest the paper by Johnson *et al.* (*Br J Surg* 1998; 85: 188–90) reporting that the higher the inferior vena cava (IVC) pressure, the greater the venous engorgement of the liver which leads to increased blood loss during liver resection.

There are three points of concern. First, the authors did not mention whether there was any correlation between IVC pressure and superior vena caval pressure, the latter of which is usually monitored as the central venous pressure during liver resection. Second, IVC pressure was measured only at certain time points instead of continuously. Surgical manipulation of the liver may distort the IVC. IVC pressure will fluctuate during liver transection and therefore simply measuring at several time points for the calculation of mean pressure may introduce unreliable results. In a similar study we measured the venous pressure continuously and calculated the mean pressure by measuring the 'area under the curve' on a plot of pressure against time. This method gives a more precise and accurate measurement of the venous pressure throughout the period of liver transection. Third, the authors described four patients with a high caval pressure who developed postoperative complications. Significant amounts of blood can be lost during mobilization of the liver, especially if cirrhotic, requiring aggressive intravenous infusion of fluid which may lead to higher caval pressure before liver transection. Normally patients who lose more blood during operation are more likely to encounter postoperative complications. Therefore, total blood loss for the entire operation as well as the blood loss during liver transection should be examined for a correlation with the morbidity following hepatectomy.

Dynamic graciloplasty for severe anal incontinence

Sir

The series of patients treated with an electrostimulated gracilis neosphincter and reported by Christiansen *et al.* (*Br J Surg* 1998; **85**: 88–91) conforms to the experiences of ourselves and others[1–3] who have encountered a number of complications, including rectal evacuatory disorders, associated with this procedure. Although the authors showed an apparent improvement in continence scores in the majority of cases, nine of the 13 patients described required revisional surgery, and three of the 13 had a poor outcome because of rectal evacuatory difficulties.

Inevitably, the use of any current continence grading scale alone is only a partial measure of outcome because it fails to assess complications and new symptoms, such as pain or constipation, that the patient may suffer after graciloplasty. Such patients may have improvements in continence, but still encounter a deterioration in overall quality of life as a result of surgery. While the visual analogue scale used by the authors allowed the patients retrospectively to report their opinion of surgical outcome, we assume that in this report continence and patient satisfaction were assessed by the surgical team treating the patient, a situation that may lead to a number of potential biases[4].

For these reasons we believe it is preferable to submit novel procedures such as the electrically stimulated gracilis neosphincter to an independent global quality-of-life evaluation using confidential questionnaires. This allows the patients to indicate whether their symptoms and lifestyle have changed after surgery to a researcher who is not part of the surgical team. Accordingly, an independently funded and managed prospective comparative trial of quality of life and cost utility of the gracilis neosphincter has now been set up at our institution[5]. We would commend this approach to all colleagues seeking objectively to evaluate the results of surgery for any new surgical procedure.

Authors' reply

Sir
We agree that a more precise description of the role of defaecatory disorders in assessment of quality of life is an important issue when treating patients with anal incontinence.

We have demonstrated that dynamic graciloplasty carries the risk of a number of different side-effects. Unexplained impaired rectal evacuation is one of the most disturbing.

As treatment for anal incontinence should improve quality of life, assessment of quality of life before surgery will, in the future, be mandatory. Until now, quality-of-life scales have not been able to place defaecatory disorders in a meaningful context for the total assessment of quality of life.

We, therefore, welcome the initiative of Eccersley and Williams to set up a prospective trial of quality of life in relation to the gracilis neosphincter procedure evaluated by independent researchers. Hopefully the quality-of-life questionnaire that the authors mention will be made available to surgeons outside the UK.

'Routine' pathological examination of the gallbladder is a futile exercise

Letter 1

Sir
The paper by Taylor and Huang (*Br J Surg* 1998; **85**: 208) was interesting and controversial. Although it makes minor economic sense, their suggestion that the practice be abandoned in favour of a 'more considered approach' relied on only six cancers correctly and intuitively suspected by the (presumably different) operating surgeons. Perhaps the same surgeons may not have done so well with 1045 early cancers. To discard 70 per cent of specimens to save £1000 plus 25 consultant-hours per year would seem trifling compared with the cost and anxiety of missing one early cancer. In an ongoing questionnaire study at this institution the details of port-site recurrences are collected. There have been surprise retrospective histological diagnoses of which the surgeons had no preoperative or peroperative intimation. Preoperative diagnosis of early gallbladder cancer is notoriously difficult and, if this cannot be confidently distinguished from chronic inflammation (97 per cent of the authors' specimens) or even dysplasia macroscopically, then histology remains mandatory. With reports of laparoscopic dissemination of *in situ* carcinomas[1] and some long-term survival[2], it is prudent not to miss such a diagnosis, rare though this will be. We would like to know whether the authors have changed their practice (or policy) in the light of their findings.

Letter 2

Sir
Taylor and Huang conclude their paper by saying that the routine histological examination of all excised gallbladders should be abandoned and a 'more considered approach adopted'. The key phrase is the last one, which could be extended much more widely within medical practice generally. As far as pathology in general is concerned, I suspect that many tests and investigations are requested for no particularly good reason and that the results do not have any significant effect on patient management. The important question that should always be asked by clinicians is 'How will the results of this test affect the management of this patient?'. If they cannot think of a reasonable answer, then arguably the test should not be requested. Tests to exclude conditions may, of course, be as valuable as those that support a diagnosis.

An increasing histopathological workload, in terms of numbers and complexity of assessment, is causing serious problems, requiring radical solutions[1]. My colleagues and I have recently suggested that the Royal College of Pathologists should examine the problem of specimens that need not be sent for histopathological examination or, if sent, require no more than macroscopic assessment[2]. Such an exercise would require wide consultation, not least with other royal colleges that should have an important role in this process. Similar considerations could, of course, be extended more widely (e.g. biochemical and radiological tests). I do hope that surgeons take up the challenge implicit in Taylor and Huang's paper and assess critically the use of clinical support services. As things stand there is a danger that the quality of work will be affected adversely by its volume, a significant part of which I believe to be unnecessary for directing patient management.

Letter 3

Sir
We read with interest the article by Taylor and Huang. The assertion that most gallbladder specimens need not be subjected to histological examination is in opposition to standard surgical teaching. We do not consider this strategy to be viable in the current medicolegal climate, with litigation cases increasing by 15 per cent per annum in the UK[1]. The authors would have to defend their policy in the context of a missed gallbladder cancer. Litigation cases where the medical records are found to be inadequate usually find in favour of the plaintiff. It would be difficult to prove that the gallbladder resection margins from a patient with unrecognized cancer were tumour-free, if no specimen was available for histological confirmation. In a review of

338 patients with cancer, in whom there had been a delay in diagnosis, Kern[2] identified two factors that made litigation more likely: cancers occurring in young and middle-aged patients and cancers associated with high cancer-specific mortality. A typical cholecystectomy patient would fall within this age group.

The desire to reduce expenditure is admirable but we think the authors are brave to implement such a policy.

Authors' reply

Sir

We agree with Zayyan and Sellu, and Bowrey *et al.*, that cost should not be of primary concern here but repeat that, based on current evidence, dysplasia and early cancers (i.e. *in situ* and T_1 tumours) require only simple cholecystectomy.

Both papers quoted by Zayyan and Sellu confirm this view. We have found no data to suggest that excision of port sites after uncovering a T_1 tumour affects outcome. The accurate distinction between these early conditions macroscopically and microscopically does not, therefore, alter the management of the patient.

In Zayyan and Sellu's study, it is unclear what is meant by 'surprise retrospective diagnoses'. Was cancer not diagnosed at the initial histological examination and only when re-examined after recurrence was found? If so, what was the value of the pathologist's involvement and should all specimens be kept so that, if port-site recurrence is found, the diagnosis can be confirmed merely for surgeon satisfaction, with no change in patient management?

When a routine specimen arrives at the pathology laboratory it is examined macroscopically by a pathologist, often a trainee, and standard sections are taken from the fundus and neck (not the surgical margin). Further sections will be cut only if there is a suspicious area. Surgical trainees and consultants might be trained to the same standard as a pathology trainee in recognizing macroscopic abnormalities of the gallbladder.

Medicolegally a surgeon would not be deemed negligent if any action were accepted by a responsible body of medical opinion (Bolam principle). If the Royal Colleges of Surgeons and Pathologists could agree on guidelines and a protocol, then surely the courts would be satisfied?

We recommend that careful inspection of the gallbladder should be carried out after excision and must include opening the specimen to examine the mucosa. Surgeons should record operative findings in greater detail and be familiar with features that merit formal histological examination: (1) discrete lesion (e.g. polyps, irregular nodules or ulcerated areas), and (2) diffuse infiltration (e.g. firm, thickened and indurated wall with gritty consistency, or penetration into the liver bed, or spread to the porta hepatis lymph nodes).

Activated protein C resistance: the commonest hereditary hypercoagulation disorder

Letter 1

Sir

We read with interest the leading article by Schuster and Jentschura (*Br J Surg* 1997; **84**: 1633–5) of a patient with activated protein C (APC) resistance who presented at an advanced age with mesenteric venous thrombosis. We had a similar experience with a 54-year-old man whose first presentation was with mesenteric venous thrombosis requiring small bowel resection and anastomosis. Subsequent thrombophilia screening showed him to be homozygous for factor V Leiden (APC resistance). Our patient has a strong family history of thrombosis with his late mother, two aunts and a sister all having had recurrent episodes of deep vein thrombosis.

Previously reported studies[1–5] suggest that between 9 and 62 per cent of cases of primary mesenteric venous thrombosis have no underlying cause found. With the discovery of APC resistance as the commonest hereditary coagulation disorder, the incidence of idiopathic mesenteric venous thrombosis should be much lower in future. We suggest that with screening of the relations of those with APC resistance, and prophylatic anticoagulation of those affected, there should be a reduction in the incidence of this condition.

Letter 2

Sir

We enjoyed the leading article by Schuster and Jentschura. Our comments concern the association of factor V Leiden with 'venous' leg ulceration. Chronic venous insufficiency leading to 'venous' leg ulcers is a significant medical problem. The prevalence of leg ulcers in one study of 92 100 subjects aged over 40 years was 0·38 per cent[1]. Up to 72 per cent of patients with leg ulcers have detectable venous insufficiency[2]. In more than 50 per cent of all leg ulcers venous insufficiency is either the sole or the predominant cause.

Factor V mutations are now known to be responsible for a higher proportion of deep venous thrombosis (DVT) cases than previously thought[2,3]. Many affected patients would progress to venous insufficiency and ulceration. In 70–90 per cent of cases the activated protein C resistance (APCR) phenotype is caused by a single nucleotide change of guanine to adenine at position 1691 of the factor V gene[4,5]. Factor V Leiden[4] and associated APCR have been found in about one-quarter of all patients with venous leg ulcers.

We sugest that venous ulceration is a reason for suspecting APCR due to variant factor V. Affected patients are candidates for recurrent thrombosis and progressive disease[6]. Their relatives have a higher susceptibility than normal as well. The presence of venous ulceration, even without any history of DVT, should be added to the possible indications for screening for factor V Leiden. Similarly, studies are required to establish whether selected patients would benefit from preventive therapy to avoid further deterioration of the venous condition. This could potentially help in healing ulcers and prevent recurrences.

Authors' reply

Sir

We appreciate the comments from Khogali and colleagues regarding the similar findings of APC resistance in a patient with mesenteric vein thrombosis. As noted in our article we propose screening measures for patients who present with an unusual location of thrombosis.

An interesting aspect is raised by Sulaiman-Shoab concerning venous leg ulceration and APC resistance. DVT remains an important cause of venous leg ulcers but can be masked by the diagnosis of chronic venous insufficiency. We agree that additional studies are required to protect the patient with venous leg ulcers from further problems due to APC resistance. In addition to prophylactic anticoagulant therapy special attention should be directed towards the offspring of these patients. Hopefully, cost-effective screening of patients and relatives will be available in the near future. The incidence of idiopathic causes of venous thrombosis is likely to decrease further as the detection of APC resistance becomes part of the daily laboratory routine.

Laparoscopic stoma formation for faecal diversion

Sir

We read with interest the article by Hollyoak *et al.* (*Br J Surg* 1998; **85**: 226–8) reporting the results of a study comparing laparoscopic and open techniques of stoma formation to defunction diseased colon. Fifty-five patients underwent either laparoscopic mobilization of a bowel loop before stoma formation or a midline laparotomy to mobilize an appropriate loop. The method of patient selection was not stated. The authors failed to mention a technique that is simpler, quicker and more commonly used: the fashioning of a loop or end colostomy via a small transverse incision at the desired site[1]. The bowel can usually be exteriorized without need for mobilization and a colostomy formed. This obviates the need for a laparotomy or the use of a pneumoperitoneum, thereby reducing pain, operating time and morbidity.

We accept that, when there are adhesions from previous surgery or widespread intraperitoneal disease, identification and mobilization of an appropriate loop may not be possible. Only in this minority of patients is a laparotomy or a laparoscopic approach required. As most defunctioning colostomies can be effected without a laparotomy, it would have been more appropriate to have compared laparoscopic colostomy formation with stoma formation through a small transverse incision. This study seems to represent a rather overzealous application of new technology.

Author's reply

Sir

We thank Marshall and McPartlin for their comments and agree that the use of a single transverse incision to create a transverse colostomy is the method of choice for this particular stoma, but believe that a transverse colostomy is an inferior stoma. It is sited in the upper abdomen, defunctions poorly if brought out as a loop and has the propensity to prolapse. The ileostomy or sigmoid colostomy are preferred stomas.

In the thin patient with no adhesions it may be possible to identify and exteriorize the terminal ileum via a small trephine. According to anecdotes, the proximal and distal limbs may be confused and the distal limb becomes spouted. A laparoscopic approach enables quick and certain identification and prevents this problem.

With a sigmoid colostomy it is hard to believe that the sigmoid can be safely brought out through the anterior abdominal wall without mobilization of the lateral peritoneal reflection. This can be performed through a limited transverse incision over the stoma site but this incision is somewhat large. In most of our patients a laparoscopic mobilization was straightforward to perform (even in the presence of adhesions) and the only incision over the stoma site was for the trephine. Furthermore, if a stoma is brought out through a transverse incision, the skin trephine is not circular and angulation of the mucocutaneous junction results. This leads to skin furrowing which makes sealing of appliances more difficult, especially in overweight patients.

Lateral rectal ligaments contain important nerves

Sir

We endorse the presence of the lateral ligament demonstrated by Rutegård *et al.* (*Br J Surg* 1997; **84**: 1544–5). The lateral ligaments are closely inter-related to the pelvic plexus which is a fenestrated rectangular plate of sympathetic and parasympathetic fibres (*Fig. 1*). This provides innervation to the bladder, ureter, prostate, seminal vesicles, membranous urethra and corpora cavernosa via anterolateral branches, and to the distal rectum via medial branches[1]. Conceivably, the nerve fibres elegantly illustrated by the authors by immunohistochemistry were the rectal branches of the pelvic plexus. It is only the medial segment of the lateral ligament that is included in the resection during rectal cancer surgery[2]. Before sharp dissection of the lateral ligament we routinely find the location of the plexus by tracing the exposed hypogastric nerve or direct palpation. The pelvic plexus is, therefore, rarely injured during the division of the lateral ligament. Partial injury of the pelvic plexus results in temporary loss of genitourinary function.

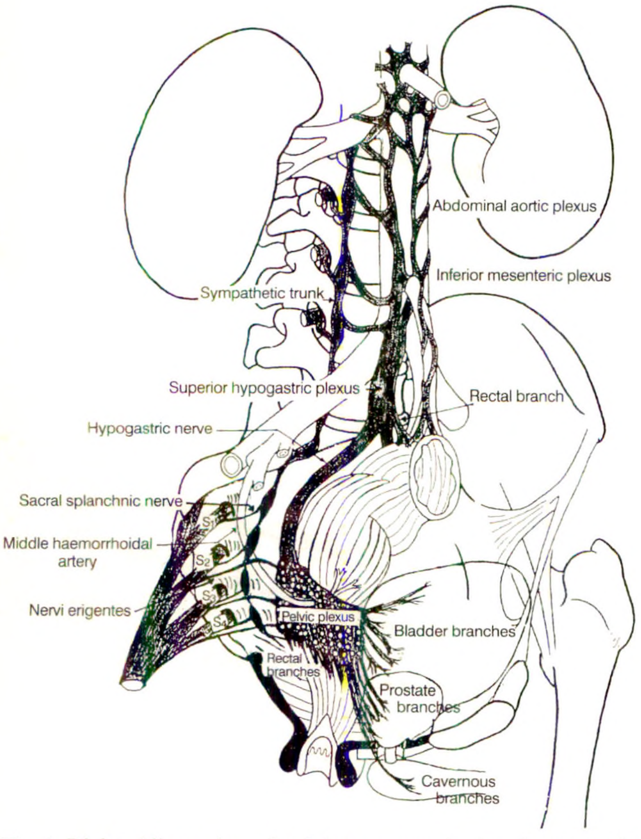

Fig. 1 Right oblique view of pelvic organs and related autonomic neuroanatomy

The periprostatic plexus represents a further challenge for colorectal surgeons endeavouring to perform autonomic nerve-preserving lower rectal cancer surgery. The periprostate plexus, running between the anterolateral rectal wall and the prostate, is vulnerable to inadvertent dissection which results in sexual dysfunction[3].

Whether the middle rectal artery is included in the lateral ligament or not is of little clinical significance because its small size allows easy control by cautery.

Authors' reply

Sir

We appreciate the comments from Liang *et al.* and agree with their description of the nerve anatomy. Their illustration has the advantage of clearly showing the sympathetic trunk which can often be visualized even in the presacral area but may give rise to the misunderstanding that the hypogastric nerves and the pelvic plexuses lie close to the rectal wall; in fact they can usually be found on the pelvic side wall.

Perioperative allogeneic blood transfusion does not cause adverse sequelae in patients with cancer: a meta-analysis of unconfounded studies

Letter 1

Sir

May I be allowed to comment on the apparent disregard of scientific objectivity and use of inappropriate methodology by McAlister *et al.* (*Br J Surg* 1998; **85**: 171–8). The authors found six randomized trials and two prospective cohort studies eligible for a meta-analysis investigating perioperative allogeneic blood transfusion and adverse sequelae in patients with cancer. Their conclusion, that there is no increased risk of clinically important adverse sequelae, cannot be drawn from the analysis.

The six randomized trials are graded from 1 to 3 on the Jadad scale. In another meta-analysis[1] five of the same six studies were categorized as level 1 (strong convincing data from large randomized trials). There is, however, discrepancy in the methodology, presentation of results and conclusion of the present meta-analysis. First, the authors claim that allogeneic blood transfusion does not increase the risk of postoperative infectious complications. This conclusion cannot be drawn as all the included studies separately demonstrated a significant increased rate of infectious complications in such patients compared with comparable non-transfused patients.

Instead, the discrepancy between the studies was whether the use of autologous or leucocyte-depleted blood could minimize this difference. The authors stressed that the elected trials using autologous blood transfusion or leucocyte-depleted packed cells acted as the control arm. This is true but they did not discuss the important aspect of the analysis where two different immunogenic transfusions are used. Furthermore, in their presentation of results (for example, *Table 4*) they confused patients being transfused with control blood and non-transfused patients as well as mixing infectious complications in different ways (for example, in some of the studies they included pneumonia and in others they did not).

In the investigation of results the authors found a summary risk ratio of 1·63 for postoperative infections, suggesting an increased risk. They then excluded two of the studies, claiming them to be heterogeneous and concluded that the risk factor was 1·0, indicating no risk.

The two excluded trials[2,3] were prospective randomized trials of patients undergoing colorectal surgery and randomized to receive leucocyte-depleted or non-depleted blood if transfusion was indicated. Patients with differing diagnoses were evenly distributed between the two transfused groups. It did not matter, therefore, that fewer patients had rectal cancer than in other trials.

McAlister *et al.* made major criticisms of the excluded studies for not transfusing control patients with allogeneic blood, whereas in other trials '10–35 per cent of control patients received crossover blood products'. This criticism is unfair as in the Jensen trials the control patients, according to the terminology of McAlister *et al.*, received leucocyte-depleted blood (which is also allogeneic) and the 'treatment' group received blood with leucocytes, i.e. blood with potentially immunosuppressive effects. The fact that only 1 per cent of control patients received crossover blood products is not a criterion for heterogeneity or exclusion. It means that only 1 per cent of patients received the inappropriately randomized blood product (compared with 10–35 per cent of patients in the other trials).

This meta-analysis does not, therefore, contribute further clarification concerning the adverse effects of blood transfusion.

Letter 2

Sir

A distinguished critic of meta-analysis, John Bailar, has written that meta-analysis is characterized by '. . . the false appearance of objectivity but consistent bias in the studies selected for analysis, heterogeneity in the effects compared . . . and lack of sufficient knowledge on the part of the meta-analyst to interpret results correctly . . .'[1]. In an article giving evidence for each of these points, McAlister *et al.* conclude 'there is no evidence that allogeneic blood transfusion increases the risk of clinically important adverse sequelae in patients with cancer undergoing surgery.'

The authors exclude a randomized trial in patients undergoing cardiac surgery demonstrating that leucocyte-depleted blood reduces postoperative infection rates substantially and postoperative mortality by more than twofold, for the scientifically indefensible reason that it does not involve cancer patients[2,3]. They proceed further to exclude from their final risk estimates two of the strongest studies that contradict their conclusions, using arbitrary mathematical criteria for this decision[6,8]. This enables them to achieve a statistically non-significant risk ratio. The authors, therefore, reach their conclusions only after dismissing three[3–5] of the six extant randomized studies of transfusion immunomodulation. Perhaps coincidentally, all three studies eliminated contradict the conclusions of McAlister *et al.* Excluding these studies, they none the less choose to combine in their analysis studies with treatment arms of either autologous transfusion[6,7] or leucocyte-depleted transfusions[4,5,8]. These treatments are not immunologically[9] or clinically equivalent. Such results should not be pooled without further analysis in this manner.

Finally, it may be worth pointing out that generally accepted criteria for evaluating causality include (1) epidemiological evidence, (2) animal model data, (3) mechanistic studies and (4) randomized controlled trials. As the authors meaningfully discuss only the last of these subjects, and that with dismissal of half of the available data, the issue of causality cannot be even remotely addressed by their meta-analysis.

Author's reply

Sir

We followed closely the recommended protocols of the Cochrane Collaboration[1] and the NHS Centre for Reviews and Dissemination[2] in conducting this meta-analysis and, therefore, refute Dr Jensen's claim that we lacked scientific objectivity or used inappropriate methodology.

In addition to the pitfalls of meta-analysis mentioned by Dr Blumberg, another common mistake is the attempt to combine studies with widely disparate patients, protocols and outcomes to obtain a summary risk ratio. Such an analysis, which neglects between-trial heterogeneity, is clearly inappropriate[3]. One of the key aspects in the conduct of any meta-analysis is to start with a focused question, in our case whether transfusion of allogeneic blood to patients with cancer increases mortality, cancer recurrence and postoperative infection rates. As the clinic to which Dr Blumberg refers enrolled patients without cancer and did not assess outcomes we were interested in, it was excluded from the analysis although referenced.

Dr Jensen questions the use of the Jadad scale to grade the quality of the six identified randomized trials, pointing out that Blajchman[4] (in an editorial, not a meta-analysis) categorized five of the studies as level 1 studies. Level 1 evidence simply refers to evidence derived from randomized clinical trials but at no point does Blajchman discuss the methodological quality of each trial. Indeed, 'the assumption that all randomized clinical trials with a common content area are of equal quality may be erroneous'[3]. The Jadad scale is commonly used to evaluate the methodological rigour of clinical trials and was systematically developed using standard scale development techniques[5]. We felt that use of this scale was the most objective means by which to grade the quality of the included trials.

Dr Jensen seems to suggest that our findings are at odds with those expressed by Blajchman in his editorial, but Blajchman states clearly that there are 'contradictory data from the six available level 1 studies' and calls for a pooling of data from each investigator for an individual-patient data meta-analysis to determine 'whether or not allogeneic blood transfusions are associated with an increased risk of postoperative infection'[4]. I believe this conclusion is concordant with our statements that there is 'a paucity of evidence underlying claims about the hazardous effects of perioperative allogeneic blood transfusion' and that 'more studies are required before a definitive statement can be made'.

Dr Jensen asserts that all of the identified studies separately demonstrated significantly increased rates of infectious complications in transfused *versus* non-transfused patients. This comparison does not contribute to the question at hand (and the focus of our meta-analysis). Confounding conditions that are associated with both an increased likelihood of transfusion and a worse prognosis have to be taken into account. It would be incorrect to compare event rates in transfused patients to those in non-transfused patients. In the absence of trials randomizing patients to allogeneic transfusion or no transfusion, I believe the use of clinical trials that randomized patients to allogeneic transfusion or active controls (autologous or leucocyte-depleted allogeneic blood) was the only acceptable alternative. While Dr Jensen believes that we 'confused transfused and non-transfused patients', we did use the intention-to-treat principle in assigning outcomes, which is a standard approach to the analysis and interpretation of clinical trials.

Dr Blumberg suggests that we were able to obtain a statistically non-significant risk ratio only by excluding Dr Jensen's trials but the summary risk ratios (*Table 4* and *Fig. 1* of our paper) included all six trials. While Dr Jensen points to the summary risk ratio of 1·63 for postoperative infections as evidence that there is an increased risk with allogeneic transfusion, he neglects the 95 per cent confidence intervals in *Table 4*. Even when his two trials are included, the 95 per cent confidence interval for the summary risk ratio crosses one (implying that any observed difference in event rates between allogeneic and control patients was not statistically significant). The small sample sizes of these six studies mean that the available evidence is insufficient to rule out a relative increase in postoperative infection of 10 per cent (or less) from allogeneic blood. The limitations of meta-analyses with small sample sizes tend to overestimate treatment effects and we believe our conclusions are valid.

Although Dr Jensen feels we made 'major criticisms of the excluded studies', we merely pointed out possible sources of the statistical heterogeneity in the postoperative infection data. As heterogeneity refers to differences between trials, I am puzzled by the argument that the identified differences between trials do not fulfil 'criteria for heterogeneity'.

Finally, while Dr Blumberg identifies several potential sources of information on causality, we focused our attention on the highest level of evidence: the randomized controlled trial. While the other sources of information are useful in generating hypotheses, medicine is replete with examples of therapies that appeared very beneficial from epidemiological evidence, animal studies or mechanistic studies, but did not provide clinical benefits when subjected to rigorous testing in clinical trials.

Our meta-analysis was rigorously and objectively conducted, summarized the totality of the published evidence, and highlighted the paucity of evidence underlying claims of adverse sequelae from the use of allogeneic blood products.

Book reviews

Stents in Endovascular Surgery: Basic Concepts and Techniques

F. J. Criado (ed.). 278 × 215 mm. Pp. 124. Illustrated. 1996. Armonk, New York: Futura Publishing. $49.

This 120-page glossy book describes in 16 chapters some of the basic concepts involved in the placement of metallic endovascular stents throughout the vascular system: to its credit, many of the pictures are very pretty. However, there is much to be questioned in the text. The author has some interesting thoughts on training in endovascular techniques. He chooses to contradict the published guidelines from his own country and considers it unnecessary for trained vascular surgeons to embark on a full 1-year 'endovascular fellowship'. He goes on to state that 'whether surgeons only participate or are the primary operators is not critical, as long as the experience is certified', and that a knowledge of thrombolysis alone is sufficient for initial credentialling – personal experience is not critical. All this is to ensure 'the surgeon's continued pre-eminence in the treatment of vascular disease'. Sadly, these political thoughts are about as relevant to the UK as the remainder of the text. The book almost exclusively focuses on the use of the Palmaz stent, a shame as this will soon only be available in museums. Clinical indications with outcome data are strictly avoided, and there are many practices peculiar to the author's own experience. Subintimal recanalization is considered undesirable, he suggests a brachial arteriotomy for subclavian stenoses, dextran is used routinely, modern contrast agents are only to be used selectively, and stents are to be deployed in almost every case of iliac angioplasty. There are many well written, well referenced textbooks on the endovascular management of vascular disease. This is not one of them

The Pathophysiology of Pneumo-peritoneum

R. J. Rosenthal, R. L. Friedman and E. H. Phillips (eds). 240 × 158 mm. Pp. 187. Illustrated. 1998. Heidelberg: Springer. £57.

Laparoscopy and laparoscopic surgery have become frequent surgical procedures. Of necessity, laparoscopy requires pneumoperitoneum. The majority of technically related complications to laparoscopic surgery are caused by the establishment and maintenance of pneumoperitoneum. The very significant impact of this on respiration and blood flow to central and peripheral organs has not been given very much attention among surgeons. This multiauthor book provides a detailed overview of the physiological changes that are induced by pneumoperitoneum and their pathogenesis. In addition to the influence of various gases, their temperatures and the technical details of establishing pneumoperitoneum, the cardiovascular and respiratory influences are reviewed. Each chapter has a detailed reference list including clinical as well as experimental papers published in 1996 and earlier. With the frequency of laparoscopic procedures we see today it is a necessity for surgeons to be aware of and understand these pathophysiological changes. This 180-page book provides the data needed and it therefore fills a gap in the market. It will allow updating of knowledge and it should serve as a reference volume in the department library.

Ductal Carcinoma *in situ* of the Breast

M. J. Silverstein (ed.). 283 × 220 mm. Pp. 665. Illustrated. 1997. Baltimore, Maryland: Williams and Wilkins. £115.

Ductal carcinoma *in situ* of the breast (DCIS) was a rare disease before 1980, representing less than 1 per cent of all breast cancers. With the improvement in the technique of mammography and its use as a screening tool in asymptomatic women, the diagnosis is now made more frequently. At the present time, DCIS represents 15 per cent of all new breast cancers diagnosed. It is a controversial topic. There are those who argue that DCIS only rarely develops into invasive cancer, and so looking for it and treating it represents overdiagnosis. On the other hand, there are those who argue that lives can be prolonged by actively seeking it out and extirpating it.

This book is the first to gather together all the information currently available about DCIS. It attempts to be comprehensive and, despite the rapidly increasing knowledge about DCIS, is largely successful. It deals with the biology and pathology of the condition, as well as its diagnosis and treatment, bringing together the competing views of those who favour a total mastectomy and those who use minimal treatment. The evidence derived from randomized clinical trials and other evidence is 'overviewed'; much of this evidence comes from British and European sources. It also deals with the psychosocial aspects, including chapters by those with a wide experience of helping women who are well, have a mammogram, and suddenly have cancer. There are chapters by women who have suffered this sort of event so that the reader learns what it is like from the inside. I learned a great deal from this book, and will go on doing so. I shall keep it on my bookshelf so that I may go back to it on many occasions to check facts and ascertain what others have done in a particular situation. I am sure it will be a useful reference book for those who are not breast cancer surgeons, and it is an important book which must be available for consultation in every medical library.

Scientific Surgery

The British Journal of Surgery is committed to practice of surgery based on scientific evidence. Each month we will publish a list of randomized trials and meta-analyses collated from English language publications. The full list of all these references will be available in the Scientific Surgery Archive which will be held on *The British Journal of Surgery* website together with links to free Medline sites where abstracts can be accessed (see below for details). If you have published a recent randomized trial which has not been featured in Scientific Surgery, the Editors would be pleased to receive a reprint and consider its inclusion.

Randomized trials

Valentine RJ, Duke ML, Inman MH, Grayburn PA, Hagino RT, Kakish RT *et al.* Effectiveness of pulmonary artery catheters in aortic surgery: a randomized trial.
J Vasc Surg 1998; **27**: 203–12.
The authors studied 120 patients but were not able to show any advantage for routine use of pulmonary artery catheters.

AbuRhama AF, Robinson PA, Saiedy S, Khan JH, Boland JP. Prospective randomized trial of carotid endarterectomy with primary closure and patch angioplasty with saphenous vein, jugular vein and polytetrafluoroethylene: long term follow up.
J Vasc Surg 1998; **27**: 222–34.
Some 399 operations were included; both patches were associated with a reduced perioperative stroke rate, and also reduced late restenosis, especially in women.

Cascinelli N, Morabito A, Santinami M, MacKie RM, Belli F on behalf of the WHO Melanoma Programme. Immediate or delayed dissection of regional nodes in patients with melanoma of the trunk: a randomised trial.
Lancet 1998; **351**: 793–6.
In a multicentre study of 252 patients, immediate node dissection improved 5-year survival from 27 to 48 per cent in patients who had involved nodes but did not affect outcome if the nodes were clear.

Kiviluoto T, Siren J, Luukkonen P, Kivilaasko E. Randomised trial of laparoscopic *versus* open cholecystectomy for acute and gangrenous cholecystitis.
Lancet 1998; **351**: 321–5.
Sixty-three patients were randomized. In the hands of these experts, laparoscopic cholecystectomy resulted in fewer complications and a shorter hospital stay.

Hosch SB, Knoefel WT, Pichlmeier U, Schulze V, Busch C, Gawad KA *et al.* Surgical treatment of piles. Prospective, randomized study of Parks *vs.* Milligan-Morgan hemorrhoidectomy.
Dis Colon Rectum 1998; **41**: 159–64.
Postoperative pain, duration of hospital stay and time to return to work were all less after Parks' operation in this study of 34 patients.

MacRae HM, McLeod RS. Handsewn *vs.* stapled anastomoses in colon and rectal surgery. A meta-analysis.
Dis Colon Rectum 1998; **41**: 180–9.
This review included 13 randomized trials and concluded that there is little clinical difference between the two techniques.

Merad F, Hay J-M, Fingerhut A, Flamant Y, Molkhou J-M, Laborde Y. Omentoplasty in the prevention of anastomotic leakage after colonic or rectal resection: a prospective randomized trial in 712 patients.
Ann Surg 1998; **227**: 179–86.
In this multicentre trial, omentoplasty did not reduce the frequency or severity of anastomotic leakage.

Morlian BJ, Stehle P, Wachtler P, Siedhoff H-P, Koller M, Konig W *et al.* Total parenteral nutrition with glutamine dipeptide after major abdominal surgery. A randomized, double-blind, controlled study.
Ann Surg 1998; **227**: 302–8.
In the 28 patients evaluated, glutamine enriched TPN improved nitrogen balance and lymphocyte recovery, and shortened hospital stay

Lai ECS, Lo C-M, Fan S-T, Liu C-L, Wong J. Postoperative adjuvant chemotherapy after curative resection of hepatocellular carcinoma: a randomized controlled trial.
Arch Surg 1998; **133**: 183–8.
Sixty-six patients were included; the regimen of intravenous epirubicin and transarterial cisplatin actually reduced survival.

Rogers DA, Hatley RM, Howell CG Jr. A prospective, randomized comparison of traditional and laparoscopic inguinal exploration in children.
Am Surg 1998; **64**: 119–21.
In this pilot study of 18 children, there were no complications and the duration of surgery was similar for each method.

***The British Journal of Surgery* website can be found at: http://www.bjs.co.uk. In addition to details of current and previous articles featured in Scientific Surgery, the website contains details of the Editorial Team and Board, instructions to prospective authors, links to other sites (such as The Cochrane Library) and forthcoming surgical events. The Editors welcome comments and suggestions about our website, either in writing or through the website address.**

Instructions to authors

The British Journal of Surgery publishes original articles, reviews and leading articles. All manuscripts are submitted to editorial review.

An article is reviewed for publication on the understanding that the work it reports has not been submitted simultaneously to another journal, has not been accepted for publication elsewhere and has not already been published. **Any detected attempt at dual publication will lead to automatic rejection and may prejudice acceptance of future submissions.** To avoid subsequent embarrassment, please submit with your manuscript copies of any other papers, either published, in press, or submitted for consideration elsewhere, which relate to the same subject. It is essential that you submit any other publications or submissions using the same data set to the Editors to allow assessment of any potential overlap with the submission to the Journal. Indicate on the title page whether the paper is based on a previous communication to a society or other meeting. Articles and their illustrations become the property of the Journal unless rights are reserved before publication.

Send four copies of original articles and other editorial matter to: The Editor, *The British Journal of Surgery*, Blackwell Science Ltd, 25 John Street, London WC1N 2BL, UK. Telephone: 0171 404 1831. Facsimile: 0171 404 1927. Books for review should be sent to the same address.

A covering letter must accompany all submissions and must be signed by all authors. State in the covering letter whether an abstract of the work has been published and give an appropriate reference on the title page. Disclose in the covering letter any potential or actual personal, political or financial interest you may have in the material, information or techniques described in the paper. The decision to publish or withhold such information will be made by the Editors. Acknowledge all sources of financial support for the work. The first named author is responsible for ensuring that all authors have seen and approved the manuscript and are fully conversant with its contents. The Journal accepts the criteria for authorship proposed in the *British Medical Journal* (*BMJ* 1994; **308**: 39–42). When a paper has many authors (i.e. more than six), you may be asked to justify the inclusion of all names listed. Results of multicentre studies should be reported under the name of the organizing study group. Methods of recognizing contributors have been proposed (*Lancet* 1995; **345**: 668).

Disks

Following final approval of articles, you will be asked to submit the accepted version on disk. These should be IBM-compatible. An accurate hard copy must accompany each disk, together with details of the type of computer used, software, and disk system if known. **Do not justify.** Please send us digital versions of your figures. Ideally, these should be sent in native format or WMF if created in Windows. Files saved as PS, EPS, GIF and TIF may also be used, but please note that it may not be possible to modify them. Avoid using tints if possible; if they are essential, try to make them coarse. Further details can be obtained from the publisher. Disks will not be returned to authors.

Rejected manuscripts and illustrations will not normally be returned.

Ethics

The Journal publishes all material relating to human investigation and animal experiments on the understanding that the design of the work has been approved by local ethics committees or that it conforms to standards currently applied in the country of origin. The Journal further reserves the right not to publish an article on the grounds that appropriate ethical or experimental standards have not been reached. Written consent must be obtained from the patient, legal guardian or executor for publication in *The British Journal of Surgery* of any details or photographs that might identify an individual. Submit evidence of such consent with the manuscript.

Preparation of manuscripts

The British Journal of Surgery subscribes to the policy of uniform requirements for manuscripts, which is designed to permit authors to resubmit papers to journals without extensive recasting. Authors are advised to consult the *New England Journal of Medicine* 1997; **336**: 309–15, or to obtain the leaflet 'Uniform Requirements for Manuscripts Submitted to Biomedical Journals' from The Editor, *British Medical Journal*, BMA House, Tavistock Square, London WC1H 9JR, UK (cost £1.00 per copy).

Authors are responsible for the accuracy of their report including all statistical calculations and drug doses. **When quoting specific materials, equipment and proprietary drugs, state in parentheses the brief name and address of the manufacturer.** Failure to do so will result in delay in publication as the Journal believes that this information is essential for any reader who wishes to obtain similar material. Generic names should normally be used.

Original articles

Original articles should normally be in the format of introduction, methods, results, discussion. Each manuscript must have a 200-word structured abstract. Lengthy manuscripts are likely to be returned for shortening. The discussion in particular should be clear and concise and should be limited to matters arising directly from the results. Avoid discursive speculation. **Randomized clinical trials** should be clearly identified as such in the title and abstract.

Reviews

The Editorial Board of *The British Journal of Surgery* encourages submission of review articles on topics of interest to its readers. Any topic will be considered, but priority will be given to those addressing a major current problem. The author of each accepted review will receive an honorarium. Potential authors are advised to contact: Mr J. A. Murie, University Department of Surgery, The Royal Infirmary, Edinburgh EH3 9YW, UK.

Leading articles

The Editors commission signed leading articles which are 600–900 words in length and address controversial topics of current interest. They should be supported by no more than ten key references. Submissions may be subjected to external review and assessment by the Editorial Board before acceptance. The Editors retain the right to alter style and shorten material for publication. An honorarium is payable on publication.

Correspondence

The Editors welcome topical correspondence relating to articles published in the Journal. Letters should not exceed 250 words and should be typed double-spaced.

Typescripts

Manuscripts must be clearly reproduced with adequate space for editorial notes. **Type or print the text on one side of sheets of A4 paper (210 × 297 mm) with double spacing and 4-cm margins. Manuscripts that do not conform to these requirements will be returned to you for recasting.** Begin each section (abstract, introduction, patients and methods, results, and discussion) on a new page.

Title page

On the title page give: (1) the title of the article; (2) the name and initials of each author; (3) the department and institution to which the work should be attributed; (4) the name, address, and telephone, facsimile and e-mail numbers of the author responsible for correspondence and to whom requests for reprints should be addressed; (5) sources of financial support; and (6) the category in which the manuscript is being submitted (original article, review etc.).

Abstract

This should be not more than 200 words on the second page of the manuscript and be presented in a structured format. **Background:** state why the study was done, and its main aim; **Method:** describe patients, laboratory material and other methods used. Clearly identify the nature of the study: randomized controlled trial, retrospective review, experimental study, etc. **Results:** state the main findings of the study; include important numerical values. **Conclusion:** state the main conclusion drawn from the results. Controversial or unexpected observations may be highlighted, but keep this section brief. Write the abstract in clear prose.

Tables and illustrations

Submit three copies of all illustrations and tables. Type each table on a separate page with an appropriate brief title. Line drawings are acceptable as clear black on white graphics, computer printout or photocopies. Submit radiographs, photomicrographs, etc unmounted in the form of glossy prints, original transparencies or negatives. If you include photocopies, they should be of sufficient quality to enable the Journal's referees to judge their content and value. Label each illustration on the reverse side giving its number (to correspond with its reference in the text) and the name(s) of the author(s); indicate the top of the illustration. Include a measure of magnification of photomicrographs. Illustrations should be drawn and labelled appropriately for reduction to one or two column widths of the Journal. Include explanations of symbols and shading in the legend. Survival curves should be accompanied by a table giving the actual numbers of patients involved. Include in the legends to illustrations and the footnotes to tables brief but comprehensive explanations of all the information presented. Look at recent issues of the Journal for examples of accepted layout. If a table or an illustration has been reproduced from a published work give the original source in full. Obtain permission to use published work from the original author and the publisher before submission.

Abbreviations

Use abbreviations sparingly. Terms that are mentioned frequently may be abbreviated but only if this does not impair comprehension by the reader. Use abbreviations consistently throughout the text and clearly define each one on first use.

Numbers and units

Use the decimal point, not a comma, e.g. 5·7. Use a space and not a comma after thousands and multiples thereof, e.g. 10 000. Use SI units (International System of Units) except for the measurement of blood pressure (mmHg). Where measurements were made in non-SI units, give the actual values and units, with SI equivalents inserted in parentheses at appropriate points.

Statistics

For detailed guidance on the handling of statistical material, consult *Br J Surg* 1991; **78**: 782–4. In evaluating a manuscript the Editors and statistical referees will consider the design of the study, the presentation and analysis of data and the interpretation of results.

Design

Set out clearly the objectives of the study, identify the primary and secondary hypotheses, and the chosen end-points, and explain the rationale for the choice of sample size. Investigators embarking on randomized controlled studies may wish to consider the CONSORT statement (*JAMA* 1996; **276**: 637–9).

Presentation

Whenever possible use graphical presentation to illustrate the main findings of a study. The use of standard deviation and standard error should be clearly distinguished. Do not use the '±' symbol; these statistics should be presented in parentheses after the mean value.

Analysis

Clearly describe which methods were used for which analyses; any methods not in common usage should be supported by references. Report results of statistical tests by stating the value of the test statistic, the number of degrees of freedom and the *P* value, e.g. '*t* = 1·34, 16 d.f., *P* = 0·20'.

Actual *P* values should be reported to two decimal places, especially when the result is not significant, rather than stating 'not significant'. Whenever possible, the results of the primary analyses should be reported using confidence intervals instead of, or in addition to, *P* values.

Interpretation

Do not confuse statistical significance with clinical significance. In particular, 'negative' findings should be interpreted through the use of confidence intervals.

Beware of placing undue emphasis on secondary analyses, especially when they are suggested by an inspection of the data.

References

Type the references with double spacing in the Vancouver style (see above: Uniform Requirements for Manuscripts Submitted to Biomedical Journals). Reference to abstracts from meetings is discouraged. Reference to unpublished communications will not be accepted. Cite personal communications in the text, in parentheses. The first author is responsible for confirming the acceptability of the material quoted with the originator.

In the text, number the references consecutively by superscript: ^{1} or $^{1-3}$. References cited only in tables or figures should be numbered in sequence according to the first mention of the table or figure in the text. The sequence for a standard journal article should be: author(s); title of paper; journal name abbreviated as in Index Medicus (written in full if no abbreviation is quoted); year of publication; volume number; page numbers. For example: De Bolla AR, Obeid ML. Mortality in acute pancreatitis. *Ann R Coll Surg Engl* 1984; **66**: 184–6. The sequence for the chapters of a book should be: author(s); chapter title; editors; book title; place of publication; publisher; year of publication; page numbers. For example: Calenoff L, Rogers L. Esophageal complications of surgery and lifesaving procedures. In: Meyers M, Ghahremani G, eds. *Iatrogenic Gastrointestinal Complications*. New York: Springer, 1981: 123–63.
